Formation and quenching processes, as well as the optical emission characteristics of Xe₂Br*, centered at 440 ± 30 nm, were investigated for electron beam pumped mixtures of argon, xenon, and several different bromine donors. Three-body collisional quenching of XeBr* was identified as the primary formation mechanism for the triatomic species. Quenching rates for Xe₂Br* and XeBr* were measured and the Xe₂Br* radiative lifetime was determined to be 245 ± 30 ns.

INTRODUCTION

In recent years there has been considerable interest in the triatomic rare gas–halogen excimers. These excimers exhibit radiative transitions in the wavelength region from 260 to 650 nm. Because the triatomic rare gas–halogens have a steeply repulsive potential energy curve in the ground state, the fluorescence is inherently broadband, as compared to the narrow spectral linewidth of the diatomic excimer.

The existence of the triatomic excimers was first identified from companion fluorescence observed on the long wavelength side of the emission from their diatomic counterparts. These trimers were first viewed as a loss mechanism for the diatomic rare gas–halide lasers. It was proposed by Huestis et al. that these triatomic molecules could be employed as tunable laser media. Subsequently, electron beam excited Xe₂Cl* was shown to have optical gain within its fluorescence band. Two triatomic lasers Xe₂Cl* centered at 520 nm and Kr₂F* centered at 435 nm were demonstrated by Tittel et al.

In this paper, we describe the excited state kinetics of the triatomic rare gas halide Xe₂Br*. This excimer was investigated in order to establish the feasibility of a Xe₂Br* laser. Furthermore, the formation of Xe₂Br* represents an important loss mechanism for the XeBr* laser.

Narrow band emission from the diatomic species, XeBr* was first reported by Velazco and Setser and Brau and Ewing. XeBr* was the first diatomic excimer for which laser action was demonstrated. The fluorescence emission spectrum of the triatomic species, Xe₂Br* was recently reported by Konovalov et al.

In our experiments, the trimer Xe₂Br* was formed by electron beam excitation of high pressure mixtures of argon, xenon, and a bromine donor. Figure 1 illustrates typical fluorescence emission from an electron beam pumped mixture of Xe, Ar, and Br₂. The XeBr (B-X) emission at 282 nm, the Br* emission at 291 nm, and the very broadband Xe₂Br* emission centered at 440 nm are depicted in the figure. The fluorescence intensity and decay rate of the Xe₂Br* emission were studied as a function of gas mixture in order to determine the quenching behavior of the constituents, and the radiative lifetime of the trimer. From this data, a kinetic model for the formation and removal of the triatomic excimer was developed.

EXPERIMENTAL PROCEDURE

Mixtures of high purity argon (99.999%), (0.5 to 6 atm), xenon (50 to 900 Torr), and various bromine donor gases (0.1 to 5 Torr) in a stainless steel reaction cell were transversely pumped by an electron beam. The 10 ns long beam of 1 MeV electrons was generated by a Physics International Pulserad 110 accelerator, and typically had a maximum current density of 200 A/cm² at the optical axis of the cell. Details of the apparatus and experimental techniques employed have been described elsewhere.

The optical emission from the cell was monitored with two fast vacuum photodiodes (ITT F4000S). Interference and color glass filters were used to define the spectral region of interest (280 and 450 nm) for each diode. The photodiode signals were recorded with a Tektronix 7912 transient digitizer, with a time resolution of about 3 ns. A 0.25 m Jarrell-Ash spectrometer, in connection with

an OMA-1 optical multichannel analyzer, was used to observe temporally integrated emission spectra. Both the transient digitizer and the OMA-1 were interfaced to a DEC 11/23 minicomputer. Computer software allowed integration of the OMA data over various spectral regions, and temporal integration of the photodiode signals. Least-squares fitting to the decay of the photodiode signal permitted accurate determination of the Xe2Br* decay time as a function of the partial pressures of argon, xenon and the bromine donor.

KINETIC MODEL

From fluorescence measurements it is possible to characterize the formation kinetics, quenching processes, and donor efficiency for an excimer system. Based on the data to be presented below, and in analogy with other triatomic excimer systems which have been studied,19-25 the most likely formation route for Xe2Br* is via the diatomic excimer XeBr*, as illustrated in Fig. 2.

In the case of e-beam excitation, the primary formation mechanism for XeBr* is via a harpooning reaction between the xenon metastable Xe*, and the bromine donor RBr and ionic reactions of Xe* with Br-. Xe* is removed by a termolecular reaction with Ar and Xe to form XeBr*. The primary quenching pathways for XeBr* are radiation and possibly, reaction with a donor to form Xe2Br*. This formation channel for the trimer molecule has been observed in the case of Ar2F* by Chen et al.,19 and by Bowering et al.22

The most important reactions involving XeBr*, leading to the formation of Xe2Br* are listed in Table I. The removal of XeBr* can occur via radiative decay [Reaction (1)], as well as through interaction with the other constituents of the gas mixture [Reactions (2)-(7)]. However, only two of these reactions result in the production of Xe2Br* [Reactions (4) and (6)]. The rate constants for Reactions (4) and (6) are both of the same order of magnitude (see below), but because in most of the experiments the argon pressure is much higher than the xenon reaction, Reaction (6) dominates.

Assuming linear quenching for Xe2Br*, and neglecting a possible production channel for Xe2Br* via XeBr*, the following rate equation describing the time dependence of the Xe2Br* population is obtained:

\[
\frac{d}{dt} [XeBr^*] = (k_5 [Ar] + k_6 [Xe]) [Xe][XeBr^*] - \frac{1}{\tau_{\text{eff}}} [Xe2Br*].
\]

(1)

In this equation, the quantities in brackets (e.g., [Xe]) represents the density of that species in the gas mixture. The rate constants for the formation reaction are given by \(k_5\) and \(k_6\) (see Table I) and \(\tau_{\text{eff}}\) is the effective decay time of Xe2Br*, which will be discussed below. For sufficiently low xenon pressures, the xenon–xenon formation reaction [given as Reaction (4) in Table I] can be neglected, and Eq. (1) can be integrated to yield

\[
[Xe2Br^*](t) = k_6 [Ar] [Xe] \int_0^t [XeBr^*(t')] dt' - \frac{1}{\tau_{\text{eff}}} \int_0^t [Xe2Br^*(t')] dt'.
\]

(2)

The observed time integrated fluorescence intensities in the UV and visible \(I_{\text{uv}}\) and \(I_{\text{vis}}\) are given by

*For donor Br₂.
The constants \( C_1 \) and \( C_2 \) contain the radiative lifetimes of \( \text{XeBr}^* \) and \( \text{Xe}_2\text{Br}^* \), as well as the spectral sensitivity of the detection system. The \( \text{XeBr}^* \) population will decay to zero after sufficient time. Thus, if we set \( t = \infty \) in Eq. (2), the left-hand side is zero, and then substituting Eqs. (3) and (4) we obtain

\[
\frac{I_{\text{XUV}}}{I_{\text{XUV}}} = \frac{C_2}{C_1} (k_5 \tau_{\text{eff}} [\text{Xe}][\text{Ar}]).
\] (5)

These intensities are directly measured with the optical multichannel analyzer, when the spectra are integrated over the appropriate UV and visible wavelengths. Figure 3 shows the intensity ratio as a function of xenon pressure. The linear dependence of the intensity ratio on the xenon pressure supports the assumption that Reaction (6) is the primary production channel for \( \text{Xe}_2\text{Br}^* \).

**Formation of \( \text{Xe}_2\text{Br}^* \)**

In order to study the formation mechanism of \( \text{Xe}_2\text{Br}^* \) in detail, the time dependence of the \( \text{Xe}_2\text{Br}^* \) and \( \text{XeBr}^* \) fluorescence was investigated. The time dependence of the fluorescence signals, as measured by the photodiodes, is given by

\[
V_{\text{XeBr}^*}(t) = \alpha_1 \frac{[\text{XeBr}^*](t)}{\tau_{\text{XeBr}}}.
\] (6)

\[
V_{\text{Xe}_2\text{Br}^*}(t) = \alpha_2 \frac{[\text{Xe}_2\text{Br}^*](t)}{\tau_{\text{Xe}_2\text{Br}}}.
\] (7)

The constants \( \alpha_1 \) and \( \alpha_2 \) contain the transmission characteristics of the filters used to separate the UV and the visible fluorescence, which were very carefully determined, and the sensitivity of the photodiode for the different wavelengths. Substituting Eqs. (6) and (7) into Eq. (1), and neglecting the \( k_i [\text{Xe}][\text{Ar}] \) term as compared to the \( k_5 [\text{Xe}][\text{Ar}] \) term, we find

\[
\frac{d}{dt} V_{\text{Xe}_2\text{Br}^*} = k_5 [\text{Ar}][\text{Xe}] \frac{\alpha_2}{\alpha_1} \frac{\tau_{\text{XeBr}}}{\tau_{\text{Xe}_2\text{Br}}} V_{\text{XeBr}^*} - \frac{1}{\tau_{\text{eff}}} V_{\text{Xe}_2\text{Br}^*}.
\] (8)

The constants \( k_5 \) and \( \tau_{\text{eff}} \) can be determined by fitting the \( \text{Xe}_2\text{Br}^* \) fluorescence signal obtained by integrating Eq. (8) to the observed \( \text{Xe}_2\text{Br}^* \) fluorescence. The measured \( \text{XeBr}^* \) emission is used as input data for the integration. To insure good time synchronization between the input \( \text{XeBr}^* \) pulse and the \( \text{Xe}_2\text{Br}^* \) pulse to be fit, the same photodiode was used to obtain both signals, the interference filters were simply interchanged, leaving everything else in the experiment constant. Figure 4 shows a typical \( \text{XeBr}^* \) fluorescence pulse at 282 nm and the observed \( \text{Xe}_2\text{Br}^* \) emission at 450 nm. The dashed curve in Fig. 4 is the result of a computer integration of Eq. (8), with \( k_5 = 3.1 \times 10^{-31} \text{ cm}^6 \text{s}^{-1} \). Fits for a number of different gas mixtures, resulted in a formation constant \( k_5 \) of \((3.2 \pm 0.4) \times 10^{-31} \text{ cm}^6 \text{s}^{-1} \). This value also agrees to within 20% to the value one gets by substituting for \( C_2/C_1 \) and \( \tau_{\text{eff}} \) in Eq. (5).

Further insight into the processes leading to the formation of \( \text{Xe}_2\text{Br}^* \) can be obtained by looking at the removal of \( \text{XeBr}^* \). Neglecting the inefficient two-body quenching by the rare gases, the pertinent rate equation for the dimer can be written as

\[
\frac{d[\text{Xe}_2\text{Br}^*]}{dt} = P - [k_4 \text{[Xe]} + (k_5 + k_6) [\text{Ar}][\text{Xe}][\text{Xe}]] [\text{Xe}_2\text{Br}^*].
\] (9)

In this equation, \( P \) is the net production rate of \( \text{XeBr}^* \) and \( \tau \) is the radiative lifetime of \( \text{XeBr}^* \). In our pressure regime, the production of \( \text{XeBr}^* \) is much faster than the production of either \( \text{ArBr}^* \) or \( \text{Xe}_2\text{Br}^* \), and \( P \) can be written as

\[
P = f_1 [\text{Ar}] + f_2 [\text{Xe}].
\] (10)

The constants \( f_1 \) and \( f_2 \) represent the formation constants for \( \text{XeBr}^* \) as a result of the argon and xenon concentration in the cell. This assumption will be discussed in detail below. With the argon concentration set to zero, and taking the time dependent \( \text{XeBr}^* \) fluorescence at its peak (when the derivative is zero), one can put Eq. (9) in the following form:

\[
\frac{dV_{\text{Xe}_2\text{Br}^*}}{dt} = k_5 [\text{Ar}][\text{Xe}] \frac{\alpha_2}{\alpha_1} \frac{\tau_{\text{XeBr}}}{\tau_{\text{Xe}_2\text{Br}}} V_{\text{XeBr}^*} = \frac{1}{\tau_{\text{eff}}} V_{\text{Xe}_2\text{Br}^*}.
\] (8)
quenchers. For example, the data for various mixtures plotted against the partial pressure of each of the

The three quenching constants $k_8$, $k_{10}$, and $k_{11}$, are found by taking the slope of the Xe$_2$Br$_*$ fluorescence decay rate plotted against the partial pressure of each of the quenchers. For example, the data for various mixtures of Ar/Xe/CHBr$_3$ are shown in Figs. 7(a)–7(c). For the

Quenching by the bromine donor molecule is dependent on the particular donor species used. Those donors which we investigated were CBr$_4$, CHBr$_3$, HBr, Br$_2$, CH$_2$Br, C$_2$H$_5$Br, and C$_6$F$_4$Br$_2$. Quenching values for many of the donors studied are given in Table II. Using the quenching constants determined above, a radiative lifetime $\tau_{XeBr^*}$ of $245 \pm 30$ ns is determined from Eq. (13).

The Xe$_2$Br$_*$ peak fluorescence intensity was investigated as a function of the various components in the gas mixture. The fluorescence increased with increasing xenon pressure up to about 200 Torr, after which the fluorescence intensity saturated. No further increase was observed up to 500 Torr xenon. The peak fluorescence intensity increased linearly with argon pressure up to 5 atm after which it saturated.

The fluorescence from various donor species was studied to determine which would yield optimum Xe$_2$Br$_*$ emission. Carbon tetrabromide (CBr$_4$) had the highest fluorescence yield of the donors studied, but is a solid at room temperature, with a vapor pressure of only 0.5 Torr. In order to achieve a sufficient vapor pressure to conduct experiments, the entire cell must be heated to about 50°C. The next best donor in terms of fluorescence yield, was bromoform (CHBr$_3$), which gave about 80% of the maximum yield of CBr$_4$. Since this donor has a vapor pressure of over 20 Torr at room temperature, it was experimentally more convenient to use than CHBr$_3$. Elemental bromine (Br$_2$) demonstrated only about 30% of the output of carbon tetrabromide.
bromide. Although HBr had reasonable yield, it was very reactive and hydroscopic making it difficult to obtain useful experimental information about its properties. Figure 8 depicts the fluorescence yield of three different donors as a function of donor pressure.

**DISCUSSION**

The production process for Xe₂Br⁺ is essentially a three-body quenching process of XeBr⁺. Unlike the case of Xe₂Cl⁺, where the three-body quenching of XeCl⁺ is much larger than the production rate of Xe₂Cl⁺, the values are equal to within experimental error for Xe₂Br⁺. This means that there is a very high production efficiency for Xe₂Br⁺ from XeBr⁺, of more than 75%.

In order to explain the difference between the three-body quenching rate of XeCl⁺ and formation rate of Xe₂Cl⁺, an intermediate species, ArXeCl⁺ was suggested. No evidence was found which would suggest that an analogous molecule (ArXeBr⁺) was being formed in our experiments.

Because of the large energy difference between Xe₂Br⁺ and 2Xe + Br⁺(2P₃/₂) or 2Xe + Br⁺(2P₁/₂), the cross section for a quenching process yielding the atomic products should be quite small. Therefore, Xe₂Br⁺ formation is the only important channel for a three-body quenching reaction of XeBr⁺. As a result, the three-body quenching of XeBr⁺ by 2Ar should be negligible. Indeed, no evidence for removal of XeBr⁺ by 2Ar was found in our experiments.

For the reaction of XeBr⁺ with two Xe atoms, only the quenching constant for XeBr⁺ was measured. However, the arguments cited above for the Ar-Xe reaction hold for the Xe-Xe reaction as well. Therefore, Xe₂Br⁺ formation is the only important channel for the quenching reaction of XeBr⁺. As a result, the three-body quenching of XeBr⁺ by 2Ar should be negligible. Indeed, no evidence for removal of XeBr⁺ by 2Ar was found in our experiments.

For the reaction of XeBr⁺ with two Xe atoms, only the quenching constant for XeBr⁺ was measured. However, the arguments cited above for the Ar-Xe reaction hold for the Xe-Xe reaction as well. Therefore, it may be supposed that the production rate for Xe₂Br⁺ by this process has about the same magnitude as the quenching rate of XeBr⁺ by 2Xe.

No evidence for the production of Xe₂Br⁺ via Xe₂⁺ was observed. Even if this process does occur, its contribution to the total Xe₂Br⁺ population seems to be negligible under the present experimental conditions.

The analysis of the three-body quenching of XeBr* was founded on the assumption that the production efficiency of XeBr* was independent of both the argon and xenon pressure. If this assumption is correct, then the ratio of the production constants $f_2/f_1$ should depend only on the ratio of the excited and ionized argon and xenon species initially created by the e-beam excitation. Taking into account the different stopping powers for Xe and Ar and the energy necessary to create either Ar* or Xe*, respectively, the ratio $f_2/f_1$ should equal about three. The ratio $f_2/f_1$ which gives the best fit to Figs. 5 and 6 is 2.45. This is a reasonable agreement, and supports the assumption that the production rate $P$ depends only on the ratio of the density of excited species.

Quenching of XeBr* by electrons has been neglected in our analysis because no information about this process is available. However, calculations by Hazi et al. and experimental investigations by Trainor and Jacob for the rare gas fluorides suggest a rate constant on the order of $10^{12} \text{cm}^3 \text{s}^{-1}$ for the quenching of these molecules by superelastic collisions. Using this rate constant with XeBr* indicates that in the low pressure regions in Figs. 5 and 6, the results might be somewhat influenced by electron quenching. However, for the higher pressures, the three-body quenching strongly dominates. The excellent fit to the experimental results shown in Figs. 6 and 7 by Eqs. (11) and (12) supports the assumption that all of the important reaction rates and radiative lifetimes have been included in the model. The uncertainty in the values of $(h_2 + k_1)$ and $(h_1 + k_2)$ is partly due to the uncertainty in $f_2/f_1$, as well as from a possible error in the determination of $\tau_{32}$ and $k_2$.

The quenching constants (Table II) for CBrF, CHBr, and BrF are accurate to within about 20%. Because of the experimental difficulties associated with HBr, the reproducibility of the data for this donor was not quite as good. An error of about 30% can be estimated in this case. CBrF had to be heated to yield a reasonable vapor pressure. Thus, the donor pressure measurement was somewhat uncertain, causing an uncertainty in the quenching rate for CBrF of about a factor of 2. The fluorescence intensities observed with the different donors (Fig. 8) are not correlated with the quenching rates for each donor, indicating much different production efficiencies for XeBr* by the various donors. Only the quenching rates for the three donors yielding the most reliable results were used in the determination of the radiative lifetime of XeBr*.

From the results of these measurements, it is possible to make an estimate of the stimulated emission cross section and gain which one might expect for e-beam excited XeBr*. Using the radiative lifetime $\tau_{\text{XeBr}}$ of 245 ns, and a fluorescence emission bandwidth (FWHM) of 65 nm a cross section of about $2.5 \times 10^{-18} \text{cm}^2$ was calculated. Thus, if competing absorption effects are neglected and an excited species density of $4 \times 10^{14} \text{cm}^{-3}$ could be achieved, a gain of 1% cm$^{-1}$ would be expected.

In summary, the kinetic processes leading to the formation and removal of XeBr* in electron beam excited mixtures of Ar/Xe/RBr have been studied. A termolecular reaction involving XeBr*, Xe, and Ar has been identified as the primary formation mechanism, and the pertinent reaction rates and radiative lifetimes measured.
