SUMMARY
In kinematic time migration one maps the time, slope and curvature characteristics of seismic reflection events, referred to as reflection-time parameters, from the recording domain of the seismic data to the time-migration domain. The inverse process is kinematic time demigration. We generalize kinematic time migration and demigration in several respects: the reflection-time parameters may belong to arbitrary source–receiver offsets; local heterogeneity of the time-migration velocity model is accounted for; the mapping operations do not depend specifically on the type of diffraction-time function and the parametrization of the velocity model. Time-migration and time-demigration spreading matrices are obtained as byproducts of the mapping operations. These matrices yield a paraxial expression for the connection between midpoint and image-point gather locations of mapped reflection events. Also, we obtain the time-migration counterpart of the so-called second duality theorem in Kirchhoff depth migration. Diffractions and reflections are assumed to be without conversion, and sources and receivers are located along the same measurement surface. Our framework enables the identification of a full set of first- and second-order reflection-time parameters from time-migrated seismic data followed by a kinematic demigration to the recording domain. The idea of this route is to ‘undo’ eventual errors introduced by time migration and result in reliable estimation of recording-domain invariants, that is, parameters insensitive to the time-migration velocity model. The developed concepts associated with time migration are of interest in reflection seismic and global earth applications. Two numerical examples demonstrate the potential of kinematic time migration and demigration techniques in seismic time imaging and velocity-model building.

Key words: Image processing; Numerical approximations and analysis; Tomography; Body waves; Computational seismology; Wave scattering and diffraction.

1 INTRODUCTION
Time migration has been widely applied by the seismic processing industry for decades and still holds the position as the most frequently used imaging technique. Considering research and development, however, the situation is different: there, most of the resources are devoted to depth-migration methods. Although time migration has clear limitations with respect to lateral velocity variations (e.g. Robein 2003) it also has, in particular, two great advantages over depth migration: (i) time migration is normally a much faster process; (ii) the problem of estimating a velocity model for time migration is, in general, well posed. The final goal of the seismic processing sequence is to obtain a well focused and accurately located image in depth. However, because of the difficulties involved in estimating a reliable depth-migration velocity model and a depth image of sufficient quality, it is often preferred to perform interpretation of geological structures on time-migrated images. In this way, the ill-posed part of the imaging process can be postponed until more information is available. This probably explains why time migration is still attractive, in spite of its known weaknesses.

Time migration transforms seismic data from the domain of its recording coordinates to another domain in time, the time-migration domain. Both data domains are 5-D, assuming maximal acquisition geometry. The process has an inverse counterpart, time demigration, which transforms data from the migration domain to the recording domain. The analogous processes of depth migration and demigration are well established in the seismic literature. The combination of them to solve a number of imaging problems is referred to as a ‘unified approach to seismic reflection imaging’ in the companion

migration (in the stan-
T X 2001; Duveneck 2004). Therefore, with the introduction
this to be an often overlooked difference between time and depth
the output point and the relevant source–receiver locations. We find
time migration only at that location. On the other
directly related to a migration-velocity model in this domain. The
‘elementary diffraction time’, that is, the two-way time from source
to receiver via a single diffraction point in the subsurface, is a function
of two basic quantities, source–receiver offset and migration
aperture, which are defined specifically below. One example is the
classic double-square-root function (e.g. Claerbout 1985), which is
exact for a homogeneous isotropic medium. When assuming small
offsets or apertures, this function is well approximated by a cor-
responding single-square-root function (Hubral & Krey 1980). For
large offsets or apertures, however, it is often necessary to use more
sophisticated travelt ime functions (e.g. Alkhalifah 2000; Tsvankin
2005; Ursin & Stovas 2006). This will typically be a consequence
of lateral velocity variations or anisotropy in the underlying (depth)
medium. Because of the historical role of the classic single-
and double-square-root functions in time-migration algorithms, we find
it useful to discuss them explicitly below.

It is remarked that when performing time migration (in the stan-
dard way) to one specific output point, it suffices to evaluate the
time-migration velocity model only at that location. On the other
hand, when performing depth migration in a similar manner, a min-
imum requirement is that the depth–velocity model can be accessed
everywhere in a certain wave-propagation volume encapsulating
the output point and the relevant source–receiver locations. We find
this to be an often overlooked difference between time and depth
migration.

The classic approach to reduce noise and retrieve velocity-
sensitive information from recorded pre-stack seismic data is common-midpoint (CMP) stacking (Mayne 1962). With this
method, stacking over source–receiver offsets is done separately
for gathers of traces corresponding to a common source–receiver
midpoint. Before stacking one performs velocity analysis (Tanner &
Koehler 1969) and normal-moveout (NMO) correction. In recent
years, there has been a development of a suite of processing tech-
niques utilizing that coherent local reflection events in the record-
ning domain of the seismic data constitute a (hyper)surface, often
referred to as the common reflection surface (CRS). From such sur-
faces one can estimate time, slope and curvature characteristics of
the local events. These ‘reflection-time parameters’ (or CRS param-
eters) can be used for multi-midpoint stacking (or CRS stacking,
Jäger et al. 2001; Duveneck 2004). Therefore, with the introduction
of the reflection-surface concept the stacking process is no longer
limited to separate CMP gathers.

In CRS processing it is common to assume that the reflection-
time parameters belong to zero offset; we shall however abandon this
restriction in the current paper and allow the reference offset to be
finite (non-zero). For CRS processing in the finite-offset situation,
see, for example, Zhang et al. (2001). Reflection-time parameters
in the recording domain are invariants, that is, they are independent
with respect to the migration-velocity model in time or depth. This
property makes these parameters very attractive for the purpose of
estimating or updating such models. Recent research is utilizing
the CRS concept also in the context of time migration (e.g. Dell &
Gajewski 2011). In the time-migration domain, the CRS is generally
more well behaved and more easily identified than in the recording
domain, because of less noise, structures looking more like geology
and collapse of diffractions (fully or partially).

Based on spherically symmetric models, the analogues of stack-
ing and the notion of CMP have been developed also in global
earth applications. Here, epicentral distance plays the role of
source–receiver offset; bounce points play the role of midpoints.
Shearer (1991) pioneers the use of stacking methods for global data
sets. He introduces an approach using a reference phase to nor-
malize the amplitude and phase of each seismogram and a median
filter over nearby bins to enhance the coherence. It performs well
in practice at long periods (≥15 s) because the timing differences
due to the ellipticity and 3-D spatial variations are generally less
than the dominant period of such data. Stacking along theoreti-
cal (differential) travelt ime curves corresponding with basic Kirch-
hoff migration is further developed by Flanagan & Shearer (1998).
Alternative stacking methods have been developed and applied to
facilitate the observation of secondary phases (Deuss et al. 2000).
Chambers et al. (2005) carry out the stacking in the time-slowness
domain relative to a reference epicentral distance and also use a
convolutional model to estimate reflectivity. In the context of this
paper, the developed concepts associated with time migration have
potential global earth applications.

Pre-stack time migration and demigration have kinematic equiv-
alents referred to as ‘kinematic time migration’ and ‘kinematic
time demigration’, applicable when coherent reflection events are
present in the seismic data. The philosophy behind these techniques
is depicted in Fig. 1, for a certain constant source–receiver offset:
a reflector in depth can be considered as a continuum of diffraction
points (brown dots)—each point gives rise to an elementary
diffraction-time function (grey). The diffraction-time response of
the entire reflector has the reflection-time function (red) in the
recording domain as its envelope. In the time-migration domain,
the reflection-time function (blue) represents a continuum of all
the minima of the elementary diffraction-time functions. Kinematic
time migration is to map a local reflection event with (recording)
time T = x in the midpoint X to a new (migrated) time T' in the
point M x —the points X and M x are both located in a hori-
zontal plane, Σ. The inverse process is kinematic time demigration.
Both processes require knowledge of local slopes in the seismic data
(Douma & de Hoop 2006; Schleicher et al. 2009). In the following,
a point of the type M x , which localizes a common-image gather
of the migrated seismic data, is referred to as a ‘common-image
point’.

Fig. 1 also introduces the ‘diffraction isochron’, which is an
important concept inherent to seismic imaging. For a specific couple
Figure 1. (a) Considering a given constant offset, the collection of elementary diffraction-time functions (grey) for a given reflector in depth has the reflection-time function (red) in the recording domain as its envelope. Each output location of a classic time-migration process corresponds to minimum diffraction time between a uniquely defined diffraction point in depth and a planar horizontal reference (datum) surface, $\Sigma$. The reflection-time function (blue) in the time-migration domain represents a continuum of such elementary diffraction-time minima. Kinematic time migration is to map a local reflection event with (recording) time $T^X$ posted in the midpoint $X$ to a new (migrated) time $T^M$ in the common-image point $M^{CG}$. The inverse process is called kinematic time demigration. (b) Discrete diffraction points (brown) forming the reflector and some of the associated constant-offset ray paths (black). Also indicated are diffraction isochrons (pink), along which the diffraction time for a certain $X$ is constant and equal to the corresponding reflection time $T^X$.

Geophysical Journal International © 2012 RAS
of source and receiver locations, or equivalently, for a fixed offset and a fixed midpoint, $X$, the diffraction isochron is defined as the surface of constant diffraction time (i.e. the surface for which the diffraction time equals the constant time $T^X$ signified in Fig. 1).

The counterpart of kinematic time migration for mapping into depth, kinematic depth migration (or ‘map migration’), uses the same input reflection-time parameters to yield local reflector depth, dips, and curvatures (Shah 1973; Kleyn 1977; Hubral & Krey 1980; Gjøystdal & Ursin 1981; Ursin 1982b; Iversen & Gjøystdal 1996; Iversen 2004; Douma & de Hoop 2006; Stolk et al. 2009). It is also possible to do a corresponding time-to-depth mapping directly from the time-migration domain using image rays (Hubral 1977; Hubral & Krey 1980). This approach is, however, known to have more limited applicability than kinematic depth migration, as a result of the limitations inherent to conventional time migration. Some recent achievements in image-ray mapping are described by Tygel et al. (2012).

One can probably consider a graphical technique for migration (Bleistein et al. 2001, p. 10), applied before the introduction of computers, as the first approach to kinematic time or depth migration. By that method, a zero-offset reflector image is constructed geometrically as the envelope of semicircles. Whitcombe (1994) introduces kinematic time demigration for the zero-offset situation and demonstrates mapping of time and slope parameters under the assumption of locally constant migration velocities. Söllner & Andersen (2005) describe zero-offset kinematic migration/demigration of time and slope parameters under a ray-theoretical perspective, so that the resulting mapping equations are expressed in terms of surface-to-surface ray paraxial matrices of normal and image rays. Robein (2003, p. 435) points out that Whitcombe (1994)’s equations were published relatively recently and are thus overlooked by many users. Furthermore, he states: ‘Note, moreover, that these published equations must be updated to take account of time and space variability of the migration-velocity field in 3-D’. In the methodology part below, one key objective is to present such updated equations.

In this paper, we extend previous approaches to kinematic time migration and demigration of reflection-time parameters so that the parameter estimation and the mapping operations can be performed for any constant source–receiver offset, not just zero offset. In addition to mapping the reflection time and its slopes, we provide the option of mapping the full set of reflection-time second-derivatives. To improve accuracy the local heterogeneity of the time-migration velocity model is accounted for. The derived mapping formulas do not depend explicitly on the type of diffraction-time function and the parameterization of the velocity model.

In typical applications of the presented methodology one would start by time-migrating the seismic data using a preliminary time-migration velocity model. The purpose is to utilize the fact that identification of seismic reflection events is generally much more easily done in the migration domain than in the recording domain, even if the time-migration velocity model is not optimal. For each selected event we estimate local reflection-time parameters, which are subsequently kinematically demigrated to the recording domain. In this demigration operation one should use the same time-migration velocity model as in the original migration of the seismic data. The idea is that this will undo eventual errors introduced by the migration and result in reliable estimation of reflection-time invariants (e.g. Robein 2003). Knowing such invariants the ground is prepared for the important applications time-migration and depth-migration tomography. For an overview regarding velocity-model building in time or depth, see Robein (2003) and Jones (2010). Recent approaches to estimate the time-migration velocity model can be found in, for example, Fomel (2003, 2007), Cooke et al. (2009) and Dell & Gajewski (2011).

In the approaches to kinematic time migration and demigration presented below the time-migration velocity model is assumed known. We discuss how this model can be obtained at the very end of the methodology part, supported by two numerical examples. Our paper is focused on kinematic (or geometric) aspects of time migration and demigration. For completeness, Appendix A provides a brief treatment also of important dynamic aspects, using concepts and notation from microlocal analysis. One important observation in this context is that the kinematics of time migration is not completely detached from its dynamics. In particular, for a reliable estimation of reflection-time parameters at finite offsets in the time-migration domain it is essential that the time-migrated data have been properly compensated for stretch effects. The relevant stretch factor is introduced in Appendix A. In addition, we provide there an independent derivation of the basic conditions for kinematic time migration and demigration formulated in the main text.

In the following, we first describe the involved coordinates of the recording and time-migration domains of the seismic data, the principles of pre-stack time migration, the properties of the diffraction-time function, the underlying time-migration velocity model, and the reflection-time parameters in the two data domains. Thereafter, kinematic migration and demigration is presented in the same order as they appear in the natural application sequence outlined above, namely, with demigration coming before migration.

Table 1 gives an overview of most mathematical symbols used in the paper. To distinguish between vector and matrix entities that are zero, we use the notations $\mathbf{0}$ and $\mathbf{O}$ for, respectively, the zero vector of dimension 2 and the zero matrix of size $2 \times 2$. The symbol $\mathbf{I}$ signifies the $2 \times 2$ identity matrix. Moreover, some mathematical quantities may take the roles both as independent and dependent variables. We separate these two situations by marking the independent quantity (e.g. $x$) and the function (e.g. $\xi$) without and with a hat, respectively. In the figures illustrating the methodology, quantities belonging to the recording, time-migration and depth-migration domains are shown, respectively, in red, blue and brown.

## 2 Coordinate Systems for Recorded and Migrated Seismic Data

A fixed Cartesian coordinate system $(\xi_1, \xi_2, \xi_3)$ is used for describing the 3-D depth domain. We use the convention of collecting the first two of these coordinates in the vector $\xi$. The horizontal plane $\xi_3 = 0$ is the measurement surface, $\Sigma$, where all sources and receivers of the seismic experiment are located. For an outline of the involved lateral coordinates, see Fig. 2. The recording of seismic data can then be described in terms of the 5-D domain $(\mathbf{s}, \mathbf{r}, t)$, where $\mathbf{s}$ and $\mathbf{r}$ are two-component vectors defining the positions of any source point, $S$, and receiver point, $R$, situated along $\Sigma$, and $t$ is the recording time. The vectors $\mathbf{s}$ and $\mathbf{r}$ both belong to the Cartesian sub-coordinate system $(\xi_1, \xi_2)$. The three coordinates of a common-source (or common-shot) gather are $(\mathbf{r}, t)$, given that the source coordinates, $\mathbf{s}$, are fixed. Conversely, for fixed receiver coordinates, $\mathbf{r}$, the coordinate space $(\mathbf{s}, t)$ constitutes a common-receiver gather.

The midpoint, $X$, between source and receiver shall be specified by the two-component vector $x$. We also use half-offset coordinates,

Consider an arbitrary depth point, \(D\), with lateral coordinate vector \(\xi\) and vertical coordinate (depth) \(\zeta = z\). In a common-offset depth migration of the data \(d(h, \mathbf{x}, t)\), one computes an image \(d^{*}(h, \xi, z)\) for each half-offset \(h\). The depth-migration domain is then \((h, \xi, z)\), where \(\xi\) specifies the depth migration common-image point, \(D_{\Sigma}^{\text{CG}}\), in the surface \(\Sigma\). The point \(D_{\Sigma}^{\text{CG}}\) is located vertically above the point \(D\). The coordinates \((\xi, z)\) and \((h, z)\) define, respectively, common-offset gathers and common-image gathers of the depth-migrated seismic data.

Analogously to the above considerations, time migration of the data \(d(h, \mathbf{x}, t)\) yields a time-migrated data set, \(d^{*}(h, \mathbf{m}, \tau)\), defined in the time-migration domain \((h, \mathbf{m}, \tau)\). Here, \(\tau\) is the migration time, and the vector \(\mathbf{m}\) specifies the time-migration common-image point, \(M^{\text{CG}}\), also located in the surface \(\Sigma\). The common-image points \(M^{\text{CG}}\) and \(D_{\Sigma}^{\text{CG}}\) for time and depth migration usually do not coincide; this will be explained in the next section. A basic assumption behind the introduction of the time-migration domain is that the mapping between the coordinates \((\xi, z)\) and \((\mathbf{m}, \tau)\) is one-to-one. The migration time \(\tau\) is considered as a pseudo-depth variable, and as such, we have \(\tau = 0\) along the surface \(\Sigma\). The coordinates \((\mathbf{m}, \tau)\) and \((h, \tau)\) appear in, respectively, common-offset gathers and common-image gathers of the time-migrated seismic data.

The difference

\[
\mathbf{a} = \mathbf{x} - \mathbf{m},
\]

is referred to as the aperture vector for time migration. In the migration process, the vector \(\mathbf{a}\) spans the set of all input locations, \(\mathbf{x}\), that contributes to the image at the output location, \(\mathbf{m}\). This set of locations \(\mathbf{x}\) is commonly referred to as the time-migration aperture.

---

Figure 2. Lateral coordinates \(s, r, x\) and \(m\) of source point (S), receiver point (R), midpoint (X) and common-image point (M), respectively. Also indicated are aperture (a), half-offset (h), source-offset (h) and receiver-offset (h) vectors.

\[h = \frac{1}{2}(r - s), \quad x = \frac{1}{2}(r + s).\]  

As in Ursin (1982a). If this option is preferred, one can still utilize the equations derived in this paper, but all occurrences of \(h\) must then be substituted by \(-h\).

In the following, the recording domain is considered as \((h, x, t)\). In this domain, recorded seismic data are assumed given in the scalar form \(d(h, x, t)\). A CMP gather of the data \(d(h, x, t)\) is a subset for which the midpoint vector, \(x\), is fixed. The internal coordinates of each CMP gather are therefore \((h, t)\). Likewise, for a common-offset gather of \(d(h, x, t)\) the half-offset vector \(h\) is constant and the internal coordinates of the gather are \((x, t)\). Note that one could eventually have defined the half-offset vector with opposite sign, \(h = (s - r)/2\), as in Ursin (1982a). If this option is preferred, one can still utilize the equations derived in this paper, but all occurrences of \(h\) must then be substituted by \(-h\).
For given coordinates \( s, r \) and \( m \) we define the source-offset vector, \( \mathbf{h}^s \), and the receiver-offset vector, \( \mathbf{h}^r \), by
\[
\mathbf{h}^s = s - m, \quad \mathbf{h}^r = r - m.
\]
Using eq. (1) in eq. (3) and also taking into account eq. (2) yields
\[
\mathbf{h}^s = a - h, \quad \mathbf{h}^r = a + h.
\]

3 TIME MIGRATION OF PRE-STACK SEISMIC DATA

The traveltime from source to receiver via a diffraction point in the subsurface is a fundamental entity in seismic time and depth migration. It is common to express this two-way diffraction time, \( T^D \), as the sum of two one-way times,
\[
T^D = T^S + T^R.
\]
Here, the ‘source time’ \( T^S \) is the traveltime of a hypothetical wave (Green’s function) propagating between the source point and the diffraction point, and the ‘receiver time’ \( T^R \) is the corresponding traveltime from the receiver point to the diffraction point. The actual arguments to be chosen for the functions \( T^S, T^R \) and \( T^D \) will depend on the type of migration (time or depth) and the type of ‘common’ partial images to be created. In the following our studies are limited to symmetric source- and receiver waves, which means that (i) the underlying types of wave propagation and polarization for the one-way times \( T^S \) and \( T^R \) are the same, for example, so that both correspond to \( P \) waves or both correspond to \( S \) waves and (ii) the sources and receivers are situated on the same measurement surface, \( \Sigma \). Moreover, by considering only isolated branches of functions \( T^S, T^R \) and \( T^D \) in a common-offset context, the diffraction time for depth migration can be specified with the arguments \( (\mathbf{h}, x, \xi, z) \).

The purpose of time migration is to provide meaningful seismic images that look like geology in depth, but such that the resulting images are still constituted by traces in time. Time migration normally uses an explicit diffraction-time function. Given that a unique relationship exists between the coordinates \( (\xi, z) \) and \( (\mathbf{m}, \tau) \), the diffraction-time function can be expressed in the form
\[
t = T^D(\mathbf{h}, a, \mathbf{m}, \tau),
\]
with the aperture vector \( a \) defined in eq. (2).

Taking as input seismic data \( d(h, x, t) \) with frequency spectrum \( D(h, x, \omega) \) and also a given frequency-dependent weight function, \( W(h, \mathbf{m}, \tau, \omega) \), one can outline diffraction-stack time migration for constant offset \( h \) and output location \( (\mathbf{m}, \tau) \) by the integrations
\[
d^M(h, \mathbf{m}, \tau) = \int \int W^r(h, \mathbf{m} + a, \mathbf{m}, \tau, \omega) D(h, \mathbf{m} + a, \omega) \times \exp[-i\omega T^D(h, a, \mathbf{m}, \tau)] \, da \, d\omega,
\]
see eqs (A1)–(A3). Here, superscript * stands for complex conjugate. We note that Kirchhoff depth migration has been formulated previously (Schlumberger 2007, p. 195, eq. 5) with a frequency-independent weight function, \( K_{DS} \), which serves to compensate depth-migrated primary reflections for geometric spreading. Thereby, the depth-migrated amplitudes are anticipated to become a better measure of the reflectivity. Corresponding compensation of time-migration amplitudes is outside the scope of this paper; nevertheless, we observe that the weight functions \( W \) and \( K_{DS} \) can be connected in the time-migration domain by taking
\[
W^r(h, x, \mathbf{m}, \tau, \omega) = \frac{1}{4\pi^2} \tau \omega K_{DS}(h, x, \mathbf{m}, \tau).
\]

In 2-D and 3-D pre-stack time migration, eq. (7) integrates, respectively, over diffraction-time curves and diffraction-time surfaces.

It is common to formulate the function \( T^D \) for a single diffraction point \( D \) such that the common-image point \( M^{CG} \) will be situated vertically above \( D \) (at the projection point \( D^{CTG} \)) if the underlying depth-velocity model is homogeneous. However, when considering symmetric waves in isotropic media, Hubral (1977) showed that the points \( M^{CG} \) and \( D^{CTG} \) generally do not coincide in the presence of lateral velocity variations. Rather, the point \( D \) will be connected to the surface \( \Sigma \) by a generally non-straight and non-vertical image ray. This situation is depicted in Fig. 3. The emergence point \( M^{CG} \) of the image ray on \( \Sigma \) corresponds to minimum two-way time for the diffraction generated at the point \( D \). We therefore consider the coordinate vector \( \mathbf{m} \) of point \( M^{CG} \) defined by stationarity of the function \( T^D \), namely,
\[
\frac{\partial T^D}{\partial a}(h = 0, a = 0, \mathbf{m}, \tau) = 0.
\]

The assumption of one-to-one correspondence \( (\xi, z) \leftrightarrow (\mathbf{m}, \tau) \) mentioned above implies that the image-ray field cannot contain caustics.

For anisotropic media there are additional concerns, arising from the fact that diffraction-time functions used in classic time-migration approaches are symmetric in \( h \) and \( a \). These symmetry properties are exemplified in Section 4. In particular, if the point \( D^{CTG} \) is to be situated vertically above point \( D \) in a homogeneous anisotropic medium, the slowness surface has to be laterally symmetric in any plane containing the vertical axis. As a consequence, image-ray paths will be vertical lines for constant medium parameters. When medium parameters are varying, the ray paths will still be normal to the surface \( \Sigma \) as in the isotropic situation. This inherent constraint on slowness-surface symmetry means that a classic time-migration approach may still be adequate for transversely isotropic media with a vertical symmetry axis (VTI media) and for orthorhombic media with symmetry planes aligned with the main coordinate planes of the \( (\xi_1, \xi_2, \xi_3) \) coordinate system.

On the other hand, it is clear that the classic approach may easily yield significant time-migration errors if the slowness surface is laterally asymmetric. Such asymmetry is formed, for example, by a tilted transversely isotropic medium. To quantify to what extent lateral slowness-surface asymmetries are acceptable is not a subject of this paper. In the following, we do not introduce specific restrictions regarding heterogeneity or anisotropy. One basic requirement that always has to be fulfilled, however, is the absence of caustics in the diffraction-time field.

4 DIFFRACTION-TIME FUNCTION FOR TIME MIGRATION

We discuss the properties of diffraction-time functions used in time migration.

4.1 Diffraction-time partial derivatives

For the kinematic migration and demigration processes described below we need the diffraction time \( T^D \) and its partial derivatives evaluated for specific values of half-offset, \( h \), aperture, \( a \), image-gather location, \( \mathbf{m} \), and migration time, \( \tau \). The diffraction-time
Figure 3. Diffraction-time concept in classic pre-stack time migration, illustrated under the assumption that the involved time- and depth-migration velocity models give rise to identical diffraction-time functions: (a) diffraction-time curve (grey) for a single depth point, $D$, with the time $T^D$ marked (grey dot) for a midpoint ($X$) between selected source ($S$) and receiver ($R$) points; (b) corresponding diffraction ray paths (grey) and the associated diffraction wavefront (purple). The diffraction point $D$ is imaged at the location $M^{CIG}$ and time $\tau$ (blue dot) in the time-migration domain, for which the diffraction-time function has a minimum. The points $D$ and $M^{CIG}$ are uniquely connected by an image ray (dark blue). The vertical projection (dotted black line) of point $D$ to its lateral position in the time-migration domain, $D^{CIG}$, is indicated.

Partial derivatives are written in the notation

\[
\begin{align*}
    u &= \frac{\partial T^D}{\partial \tau}, \\
    q^h &= \frac{\partial T^D}{\partial h}, \\
    q^a &= \frac{\partial T^D}{\partial a}, \\
    u^m &= \frac{\partial^2 T^D}{\partial m^2}, \\
    u^{ha} &= \frac{\partial^2 T^D}{\partial h \partial a}, \\
    U^{hh} &= \frac{\partial^2 T^D}{\partial h^2}, \\
    U^{aa} &= \frac{\partial^2 T^D}{\partial a^2}, \\
    U^{mm} &= \frac{\partial^2 T^D}{\partial m^2}, \\
    U^{hm} &= \frac{\partial^2 T^D}{\partial h \partial m}, \\
    U^{ma} &= \frac{\partial^2 T^D}{\partial m \partial a}, \\
    U^{ah} &= U^{ha}^T, \\
    U^{hh} &= U^{hh}^T, \\
    U^{aa} &= U^{aa}^T, \\
    U^{mm} &= U^{mm}^T, \\
    U^{hm} &= U^{hm}^T, \\
    U^{ma} &= U^{ma}^T.
\end{align*}
\]
To better visualize the properties of these quantities, we introduce a seven-component column vector, \( \mathbf{\alpha} = (h_1, h_2, a_1, a_2, m_1, m_2, \tau)^T \), containing the arguments of the diffraction-time function, so that the complete set of first and second derivatives of function \( T^D \) is given by a seven-component gradient vector and a symmetric 7 \( \times \) 7 matrix,

\[
\frac{\partial T^D}{\partial \mathbf{\alpha}} = \begin{pmatrix} q^h \\ q^a \\ q^m \\ u \end{pmatrix}, \quad \frac{\partial^2 T^D}{\partial \mathbf{\alpha} \partial \mathbf{\alpha}^T} = \begin{pmatrix} U^{hh} & U^{ha} & U^{hm} & 0 \\ U^{ah} & U^{aa} & U^{am} & u^a \\ U^{mh} & U^{ma} & U^{mm} & u^m \\ 0 & u^a & u^m & u^t \end{pmatrix}.
\]

(11)

To emphasize symmetry, elements of the lower triangular part of matrix \( \frac{\partial^2 T^D}{\partial \mathbf{\alpha} \partial \mathbf{\alpha}^T} \) are only indicated by dots. It is remarked that the quantity \( u \) in eqs (10) and (11) yields the stretch of the time coordinate in time migration or time demigration of seismic data (see also Appendix A).

### 4.2 Properties of the diffraction-time function

The diffraction-time function \( T^D(h, a, m, \tau) \) has some general properties that are independent of the actual function representation. Considering symmetric diffractions, one immediate observation is that the function \( T^D \) has to be symmetric in the variable \( h \), that is, we always have

\[
T^D(h, a, m, \tau) = T^D(-h, a, m, \tau).
\]

(12)

The reason is reciprocity: the diffraction time is the same if source and receiver positions are interchanged. As a consequence, the partial derivatives with respect to half-offset coordinates vanish at zero offset,

\[
\frac{\partial T^D}{\partial h}(h = 0, a, m, \tau) = 0.
\]

(13)

Eq. (13) has the implication that also mixed partial second derivatives involving half-offset vanish for \( h = 0 \). The set of diffraction-time partial derivatives in eq. (11) at zero offset \( (h = 0) \) and generally non-zero aperture \( (a \neq 0) \) can therefore be written

\[
\frac{\partial T^D}{\partial \mathbf{\alpha}} = \begin{pmatrix} 0 \\ q^a \\ q^m \\ u \end{pmatrix}, \quad \frac{\partial^2 T^D}{\partial \mathbf{\alpha} \partial \mathbf{\alpha}^T} = \begin{pmatrix} U^{hh} & 0 & 0 & 0 \\ U^{aha} & U^{aa} & U^{am} & u^a \\ U^{mha} & U^{ma} & U^{mm} & u^m \\ 0 & u^a & u^m & u^t \end{pmatrix}.
\]

(14)

Consistently with the above discussions it is assumed that the source- and receiver-time functions \( T^S \) and \( T^R \) in eq. (5) are single-valued. We express them as

\[
T^S(h^S, m, T^S_0), \quad T^R(h^R, m, T^R_0),
\]

(15)

where \( h^S \) and \( h^R \) are source- and receiver-offset vectors (eqs 3 and 4), and \( T^S_0 \) and \( T^R_0 \) are source and receiver times corresponding to the situations \( h^S = 0 \) and \( h^R = 0 \). Since source points, receiver points and migration output locations belong to the same surface, \( \Sigma \), the migration time is related to the diffraction time via

\[
\tau \equiv T^S_0 + T^R_0 = T^D(h = 0, a = 0, m, \tau).
\]

(16)

Symmetric wave propagation implies that \( T^S_0 = T^R_0 = \tau/2 \). As a consequence, the diffraction-time function can be written in the form

\[
T^D(h, a, m, \tau) = T^S(h - h, m, \tau/2) + T^R(h + h, m, \tau/2).
\]

(17)

The standard approach in time migration is to assume a certain analytic relationship for \( T^S(h) \) and \( T^R(h) \) expressed in terms of coefficients evaluated at \( a = h = 0 \). Such coefficients have a simple relationship to the parameters of the time-migration velocity model, which has to be known.

Differentiation of eq. (17) twice with respect to \( a \) and \( h \) yields

\[
\frac{\partial^2 T^D}{\partial a \partial h^T}(h, a, m, \tau) = \frac{\partial^2 T^D}{\partial h \partial h^T}(h, a, m, \tau) \quad \text{or} \\
U^{aa}(h, a, m, \tau) = U^{hh}(h, a, m, \tau).
\]

(18)

In other words, for the function \( T^D \) in eq. (17) the matrices \( U^{aa} \) and \( U^{hh} \) are always equal. Based on eq. (18) we define a symmetric 2 \( \times \) 2 matrix

\[
S^M(m, \tau) \equiv \frac{1}{4} h^T U^{aa}(h = 0, a = 0, m, \tau)
\]

\[
= \frac{1}{4} \tau U^{hh}(h = 0, a = 0, m, \tau),
\]

(19)

which is useful in derivations below. It is referred to as the time-migration matrix. We observe that matrix \( S^M \) is a function of the three (volume) variables \( (m_1, m_2, \tau) \) and has unit of squared slowness. Matrix \( S^M \) is proportional to the wavefront curvature matrix of a wave diffracting at the depth point \( D \) (Fig. 3) and emerging to the surface \( \Sigma \) at the point \( M^{CG} \). As such, matrix \( S^M \) has to comply with the requirement that the diffracted wave field does not contain caustics. This requirement ensures, as mentioned earlier, that the correspondence between the points \( D \) and \( M^{CG} \) is one to one. On this background both eigenvalues of \( S^M \) must be positive in the context of 3-D post- or pre-stack time migration.

It is inherent to conventional time migration that the diffraction-time function \( T^D \) has one and only one apex in the coordinates \( h \) and \( a \). This apex is located at \( (h = 0, a = 0, m, \tau) \) and yields a considerably simplified set of diffraction-time partial derivatives. For \( h = a = 0 \) the gradients with respect to \( h \) and \( a \) are zero (eqs 9 and 13), and eq. (16) is satisfied. As a consequence, all mixed-term second derivatives of \( T^D \) involving \( h \) or \( a \) are zero; the same is true for all first- and second-order partial derivatives involving \( m \). In addition, we have \( \partial^2 T^D/\partial \tau = 1 \) and \( \partial^2 T^D/\partial \tau^2 = 0 \). In summary, we find that the set of diffraction-time partial derivatives at \( h = a = 0 \) has the structure

\[
\frac{\partial T^D}{\partial \mathbf{\alpha}} = \begin{pmatrix} 0 \\ 0 \\ 0 \\ 1 \end{pmatrix}, \quad \frac{\partial^2 T^D}{\partial \mathbf{\alpha} \partial \mathbf{\alpha}^T} = \begin{pmatrix} \frac{1}{2} S^M & O & O & 0 \\ 0 & \frac{1}{2} S^M & O & 0 \\ 0 & 0 & O & 0 \end{pmatrix}.
\]

(20)

### 4.3 Example 1: double-square-root function

One common realization of diffraction time is the double-square-root function based on exact traveltime equations for \( P \)- or \( S \)-wave propagation in a homogeneous isotropic medium. The diffraction time is obtained as \( T^D = T^S + T^R \) (see eq. 17) with one-way times
$T^S$ and $T^R$ specified by

$$T^S = \frac{1}{4} (a - h)^T S^H (m, \tau) (a - h),$$

$$T^R = \frac{1}{4} (a + h)^T S^H (m, \tau) (a + h).$$

(21)

Matrix $S^H$ has been defined in eq. (19). The double-square-root function $T^D$ is symmetric not only in the variable $h$ but also in $a$, so that

$$T^D(h, a, m, \tau) = T^D(h, -a, m, \tau).$$

(22)

4.4 Example 2: single-square-root function

Another example of diffraction-time functions is the single-square-root approximation. Following Hubral & Krey (1980) we can express it as

$$T^D(h, a, m, \tau) = \sqrt{\frac{\tau^2}{4} + 4a^2 S^H (m, \tau) a + 4h^2 S^H (m, \tau) h}.$$

(23)

As opposed to the double-square-root function, which uses eq. (21), the single-square-root function in eq. (23) is not exact for non-zero apertures and offsets in homogeneous isotropic media. At zero aperture or at zero offset, however, the single and double square-root formulas are identical. One can see immediately that the symmetry properties in eqs (12) and (22) hold for the single-square-root approximation.

It is easy to verify that eq. (23) exhibits the property of eq. (18) for $h = a = 0$ but not for arbitrary $h$ and $a$. The latter is explained by the underlying assumption of eq. (18), namely, that the diffraction time is expressed as the explicit sum of the two one-way times in eq. (17).

5 TIME-MIGRATION VELOCITY MODEL

The complete set of parameters required for time migration is referred to as the time-migration velocity model or to just as the time-migration velocity, in the case of a mono-parametric representation. Following common practise, the model is defined in the time-migration coordinates $(m, \tau)$, so that the model parameters do not depend on offset. To permit formulations of kinematic migration and demigration that do not rely on a particular model parametrization, we use the general form

$$V_i(m, \tau), \quad i = 1, 2, \ldots, N^V,$$

(24)

where $N^V$ is the number of parameters. One possibility is to use the symmetric $2 \times 2$ matrix $S^H$, defined in eq. (19), as a basis for defining the parameters $(V_i)$. When using conventional double-square-root or single-square-root diffraction-time functions it is sufficient to consider three model parameters, for example, $V_1 = S^H_{11}$; $V_2 = S^H_{12}$; $V_3 = S^H_{22} = S^H_{11}$.

From eq. (19) we recall that matrix $S^H$ corresponds to second-order derivatives of diffraction time with respect to aperture $a$ or half-offset $h$ at the apex point, for which $a = 0$ and $h = 0$. A natural extension of the set of model parameters in eq. (24) to $N^V > 3$ would be to define $V_i$ in terms of diffraction-time partial derivatives of higher order than two.

Matrix $S^H$ has historically been related to a location- and direction-dependent time-migration velocity $V^M(\theta^e, m, \tau)$ corresponding to small apertures and offsets, such that (Hubral & Krey 1980; Iversen & Tygel 2008)

$$\left[ V^M(\theta^e, m, \tau) \right]^2 = e(\theta^e) T^M (m, \tau) e(\theta^e).$$

(25)

Here, the directional dependency of $V^M$ is specified in terms of the two-component unit vector $e(\theta^e) = (\cos \theta^e, \sin \theta^e)^T$, which corresponds to a normalization of the aperture vector $a$. Observe that it would be formally equivalent to specify $V^M$ using instead a similar unit vector $e(\theta^e)$ obtained by a normalization of the half-offset vector $h$. It is not equally practical, though, as pre-stack time migration is commonly done separately for constant-offset sub-cubes of the seismic data set.

For a fixed location $(m, \tau)$ eq. (25) yields the time-migration ellipse with coefficients specified by the time-migration matrix $S^H$.

The restriction of function $V^M$ to small apertures and offsets comes from its relation to second-derivatives of diffraction time evaluated at $h = a = 0$, see eq. (19).

6 REFLECTION TIME

In the recording and migration domains we introduce two single-valued reflection-time functions corresponding to symmetrically reflected waves,

$$t = T(h, x), \quad \tau = T(h, m).$$

(26)

The first of these is historically known as a CRS belonging to a pre-stack seismic data set; the second function yields the corresponding CRS in the time-migration domain. The CRSs $T(h, x)$ and $T(h, m)$ can be parameterized locally in terms of reflection-time parameters, which is the subject of the following subsections. The connection between the reflection-time functions in eq. (26) and the diffraction-time function discussed previously is indicated in Fig. 1.

6.1 Reflection-time parameters in the recording domain

The vector couple $(h, x)$ specifies traces within the recording domain. In equations below we equivalently refer to such traces using the four-component column vector $\hat{x} = (h_1, h_2, x_1, x_2)^T$. For a reflection event at a given trace location, $(h, x)$, we associate a number of reflection-time parameters, namely: reflection time, $T^3 = T(h, x)$, slope (first-derivative) vectors $p^h = \partial T / \partial h, p^x = \partial T / \partial x$, and second-derivative matrices $M^{hh} = \partial^2 T / \partial h \partial h, M^{xx} = \partial^2 T / \partial x \partial x, M^{hx} = \partial^2 T / \partial x \partial h$. For a better overview the latter first- and second-derivative parameters can be collected in a four-component vector, $\hat{p}$, and a $4 \times 4$ matrix, $\hat{M}$, as follows (Ursin 1982a; Gjøystdal et al. 1984):

$$\hat{p} = \frac{\partial T}{\partial \hat{x}} = \begin{pmatrix} p^h \\ p^x \end{pmatrix}, \quad \hat{M} = \frac{\partial^2 T}{\partial \hat{x} \partial \hat{x}} = \begin{pmatrix} M^{hh} & M^{hx} \\ M^{xh} & M^{xx} \end{pmatrix}. $$

(27)

The quantities in eq. (27) shall be understood as functions of $h$ and $x$.

Reciprocity of symmetric reflections implies that

$$T(h, x) = T(-h, x).$$

(28)

As a consequence, the following partial derivatives involving half offset vanish at zero offset,

$$\frac{\partial T}{\partial h}(h = 0, x) = 0, \quad \frac{\partial^2 T}{\partial h \partial x}(h = 0, x) = 0.$$ 

(29)
These properties determine the classic CRS parameters (e.g. Ursin 1982a; Duveneck 2004) and yield vector $\mathbf{p}$ and matrix $\mathbf{M}$ as

$$\mathbf{p} = \begin{pmatrix} 0 \\ p^t \end{pmatrix}, \quad \mathbf{M} = \begin{pmatrix} M^{hh} & O \\ O & M^{mm} \end{pmatrix},$$

(30)

where all parameters correspond to $(h = 0, x)$.

The reflection-time parameters constituting the second-derivative matrix $M^{mm}$ evaluated for $h = 0$ have a particular interpretation in terms of NMO velocity. To aid this interpretation we introduce a $2 \times 2$ 'NMO matrix' with the unit of squared slowness,

$$S^{NMO}(x) = \frac{1}{4} T(h = 0, x) M^{hh}(h = 0, x).$$

(31)

In general there are no restrictions on the signs of the eigenvalues of matrix $S^{NMO}$. If both eigenvalues are positive, however, it is useful to relate matrix $S^{NMO}$ to a direction-dependent and surface-specific NMO velocity $v^{NMO}(\theta, x)$ associated with small offsets, such that (Hubral & Krey 1980; Iversen 2006)

$$v^{NMO}(\theta^h, x)^2 = \mathbf{e}(\theta^h)^T S^{NMO}(x) \mathbf{e}(\theta^h).$$

(32)

Here, $\mathbf{e}(\theta^h)$ is the unit vector $(\cos \theta^h, \sin \theta^h)^T$ corresponding to normalization of the vector $\mathbf{h}$. In the case of a fixed midpoint location, $x$, eq. (32) constitutes the NMO ellipse (Grechka & Tsvankin 2002). The association of parameter $v^{NMO}$ with small offsets comes from the connection to second-derivatives of reflection time evaluated at zero offset (eq. 31).

Matrix $S^{NMO}$ is a function of the two (surface) variables $(x_1, x_2)$. As such, it is essential to recognize that matrix $S^{NMO}$ is a surface function, in contrast to the time-migration matrix, $S^M$, which is a volume function. By imposing strong limitations on the shape of (depth) reflectors, however, it is possible to consider also the NMO matrix (and corresponding angle-dependent NMO velocity) as a volume function, that is, as a single-valued function of the variables $(x_1, x_2, t)$. The key point here is that normal rays from reflectors do not form caustics.

Using eq. (30) one can restate Ursin’s (1982a) approximation of the CRS with coefficients evaluated at zero offset ($h = 0$) and a reference CMP location $(x = x_0)$ as

$$T(h, x)^2 = \left[ T^x + (x - x_0)^T \mathbf{p} \right]^2 + T^M \left[ h^T M^{hh} h + (x - x_0)^T M^{mm} (x - x_0) \right].$$

(33)

6.2 Reflection-time parameters in the time-migration domain

In the time-migration domain, each trace is uniquely specified by the vector couple $(\mathbf{h}, \mathbf{m})$ or by the equivalent four-component vector $\mathbf{m} = (h_1, h_2, m_1, m_2)^T$. For a migrated reflection event at a certain trace location, $(\mathbf{h}, \mathbf{m})$, we consider the following reflection-time parameters: migrated reflection time, $T^M = T(h, \mathbf{m})$, slope vectors $\psi^h = \partial T^M / \partial h$, $\psi^m = \partial T^M / \partial \mathbf{m}$, and second-derivative matrices $\mathbf{M}^{hh} = \partial^2 T^M / \partial h^2$, $\mathbf{M}^{mm} = \partial^2 T^M / \partial \mathbf{m}^2$, and $\mathbf{M}^{hn} = \partial^2 T^M / \partial h \partial \mathbf{m}$. As in the recording domain, it is convenient to assemble the first- and second-derivative parameters in a four-component vector and a $4 \times 4$ matrix,

$$\mathbf{\psi} = \frac{\partial T^M}{\partial \mathbf{m}} = \begin{pmatrix} \psi^h \\ \psi^m \end{pmatrix}, \quad \mathbf{M} = \frac{\partial^2 T^M}{\partial \mathbf{m}^2} = \begin{pmatrix} \mathbf{M}^{hh} & \mathbf{M}^{hm} \\ \mathbf{M}^{mh} & \mathbf{M}^{mm} \end{pmatrix}.$$

(34)

The parameters in eq. (34) are considered functions of $\mathbf{h}$ and $\mathbf{m}$.

As will be proved in the derivation of eqs (61) and (62) below, the entities $\psi^h$, $\mathbf{M}^{hm}$, and $\mathbf{M}^{mm}$ are zero when $\mathbf{h} = 0$. The natural definition of (zero-offset) CRS parameters in the time-migration domain is therefore

$$\mathbf{\psi} = \begin{pmatrix} \psi^h \\ \psi^m \end{pmatrix}, \quad \mathbf{M} = \begin{pmatrix} \mathbf{M}^{hh} & \mathbf{0} \\ \mathbf{0} & \mathbf{M}^{mm} \end{pmatrix},$$

(35)

where all parameters are evaluated for $(h = 0, \mathbf{m})$. An ideal pre-stack time-migration result would imply that the entities $\psi^h$, $\mathbf{M}^{hm}$, and $\mathbf{M}^{mm}$ are zero for all $(h, \mathbf{m})$. When this is not the case one can use observations of such parameters to update the time-migration velocity model, applying the so-called extension principle (Stolk et al. 2009).

The slope vector $\mathbf{\psi}^m$ of the reflection in the time-migration domain is connected to the reflector normal in the depth-migration domain. This reflector normal can be obtained after a simultaneous construction of the image ray and (depth) velocities along it (Hubral & Krey 1980; Cameron et al. 2007; Iversen & Tygel 2008; Tygel et al. 2012). Using also the matrix $\mathbf{M}^{mm}$ it is possible to estimate the reflector curvature.

As in eq. (33) one can form an approximation of the CRS in the time-migration domain using the coefficients in eq. (35), corresponding to zero offset ($h = 0$) and a reference common-image gather location $(\mathbf{m} = \mathbf{m}_0)$, such that

$$T(h, \mathbf{x})^2 = \left[ T^M + (\mathbf{m} - \mathbf{m}_0)^T \mathbf{\psi}^m \right]^2 + T^M \left[ h^T \mathbf{M}^{hh} h + (\mathbf{m} - \mathbf{m}_0)^T \mathbf{M}^{mm} (\mathbf{m} - \mathbf{m}_0) \right].$$

(36)

7 KINEMATIC TIME DEMIGRATION

We consider the situation that a pre-stack seismic data set has been migrated using a known time-migration velocity model, $(V_i)$. This model is not necessarily the optimal one, but it is assumed sufficiently accurate to yield well-defined coherent reflection events within common-offset subsets of the data. We further assume that a picking process has been applied, and that a set of reflection-time parameters, as specified in eq. (34), has been estimated. These known reflection-time parameters shall now be mapped from the migration domain to the recording domain by kinematic time demigration, to yield the output parameter set in eq. (27). The process relies on the computation of first- and second-order partial derivatives of the known diffraction-time function, $T^D$, see eq. (10). We shall need access to first- and second-order partial derivatives of each model parameter $V_i$ with respect to the coordinates $\mathbf{m}$ and $\tau$ within the time-migration domain. The flow of the kinematic time-demigration process is outlined in Fig. 4.

In a demigration of parameters corresponding to migrated reflection time $T(h, \mathbf{m})$ the output trace location $(\mathbf{h}, \mathbf{m})$ is assumed to have a single-valued relationship to the input trace location $(\mathbf{h}, \mathbf{m})$ such that

$$\mathbf{x} = \mathbf{x}(\mathbf{h}, \mathbf{m}).$$

(37)

Because of the functional relationship in eq. (37), the aperture vector $\mathbf{a}$ in eq. (2) will also be a function of $\mathbf{m}$ and $\mathbf{h}$, given by

$$\mathbf{a} = \mathbf{a}(\mathbf{h}, \mathbf{m}) = \mathbf{x}(\mathbf{h}, \mathbf{m}) - \mathbf{m}.$$ 

(38)
7.1 Basic conditions

Consider now a reflected wave

\[ d(h, x, t) = A(h, x)s[t - T(h, x)] \tag{39} \]

with amplitude \( A(h, x) \), traveltime \( T(h, x) \), and wavelet \( s(t) \). We let \( S(\omega) \) denote the Fourier transform of \( s(t) \). When the time-migration eq. (7) is applied to this data for fixed coordinates \((h, m, \tau)\), we obtain

\[ d^M(h, m, \tau) = \int W^m(h, m + a, m, \tau, \omega) A(h, m + a) \times S(\omega) \exp \left\{ -i\omega \left[ T^D(h, a, m, \tau) - T(h, m + a) \right] \right\} da \, d\omega, \tag{40} \]

since \( x = m + a \). Furthermore, for \( m \) constant we have \( \partial / \partial x = \partial / \partial a \). Applying the method of stationary phase (e.g. Treves 1980; Bleistein 1984; Stamnes 1986) and using that \( \tau = T(h, m) \), it follows that the stationary point \( \hat{a}(h, m) \) of the aperture integral in eq. (40) satisfies the conditions

\[ T(h, \hat{x}) = T^D(h, \hat{x} - m, m, T(h, m)), \tag{41} \]

\[ \frac{\partial T}{\partial x}(h, \hat{x}) = \frac{\partial T^D}{\partial a}[h, \hat{x} - m, m, T(h, m)]. \tag{42} \]

An independent derivation is given in Appendix A. For each constant half-offset vector, \( h \), eqs (41)–(42) express, first, that the time of the diffraction-time function must equal the reflection time corresponding to the output trace location \((h, x) = [h, \hat{x}(h, m)]\) and, secondly, that the diffraction-time function is required tangential to the reflection time branch at the same location. The two conditions are completely general and can thus be used for any type of diffraction-time function.

Fig. 5 outlines how a finite-offset reflection posted in the point \( M^{CIG} \) and time \( T^M \) in the time-migration domain is mapped to the point \( X \) and time \( T^X \) by time demigration to the recording domain. The reflection point \( D \) is connected to the time-migration domain via an image ray. For the idealized situation that the involved velocity models for time and depth migration yield identical diffraction-time functions, we will have consistency between kinematic time demigration (of the reflection in the point \( M^{CIG} \) at the time \( T^M \)) and kinematic depth demigration (of the reflection in the point \( D \)): the output location in the recording domain will be the same in both situations. In the kinematic depth demigration, the point \( D \) is connected to the recording domain via the reflected ray \( SDR \). Given a perfect depth-migration velocity model, so that the point \( D \) does not change with offset, the ray \( SDR \) will coincide with the normal ray \( X_0DX_0 \) in the zero-offset situation.

7.2 Demigrated position, reflection time and reflection slopes

In this and the following subsections we establish a general framework for kinematic time demigration. Details of the derivations are given in Appendix B.
In the first subsection of Appendix B we derive the so-called consistency equation

$$\frac{\partial T^D}{\partial a}[h, \hat{a}, m, T(h, m)] - \frac{\partial T^D}{\partial m}[h, \hat{a}, m, T(h, m)] = \frac{\partial T^D}{\partial \tau}[h, \hat{a}, m, T(h, m)] \frac{\partial T}{\partial m}(h, m),$$

which can be solved to provide the aperture vector, $\hat{a} = \hat{x} - m$.

Once we know this vector, the computation of the output time $T_X = T^D[h, \hat{a}, m, T(h, m)]$ (eq. 41) and the output slope vector $p^i = \frac{\partial T^D}{\partial a}[h, \hat{a}, m, T(h, m)]$ (eq. 42) is usually straightforward.

Naturally, the complexity of the algorithm required to compute $\hat{a}$ will depend on the form of the diffraction-time function, $T^D$. Some forms of $T^D$ yield analytical solutions for $\hat{a}$; others not. In particular, as is discussed further below, $\hat{a}$ can be obtained analytically under the assumption of single-square-root diffraction time and a homogeneous time-migration velocity model. For given coordinates $(h, m)$ and time $\tau = T(h, m)$, eq. (43) is considered in the form $f_i(a) = 0, i = 1, 2$, with the goal of computing a root, $a = \hat{a}$.
numerically. In this respect, one possible approach is the Newton-Raphson method, starting by assuming some trial solution for \( \hat{a} \) which complies with eq. (43) only approximately, and then iterate until consistency is achieved within some predefined numerical limit. Given a physically meaningful solution \( \hat{a} \), one can proceed to obtain demigrated time, slopes and second derivatives.

We have already seen that the slope vector \( \mathbf{p} \) can be computed from eq. (42) when vector \( \hat{a} \) is known. There is an alternative way to compute \( \mathbf{p} \), provided by eq. (B4), which can be restated as

\[
\mathbf{p}^\dagger = \mathbf{q}^\dagger + u \mathbf{\psi}^\dagger,
\]

where eq. (10) defines the involved diffraction-time partial derivatives \( \mathbf{q}^\dagger \) and \( u \). Eq. (44) relates the slope \( \mathbf{\psi}^\dagger \) in the time-migration domain to the slope \( \mathbf{p}^\dagger \) in the recording domain. Computation of the diffraction-time partial derivatives \( \mathbf{q}^\dagger \) and \( u \) requires the knowledge of the vector \( \hat{a} \). Similarly, eq. (B7) shows that the slopes \( \mathbf{\psi}^\dagger \) and \( \mathbf{p}^\dagger \) are related by

\[
\mathbf{p}^\dagger = \mathbf{q}^\dagger + u \mathbf{\psi}^\dagger,
\]

with \( \mathbf{q}^\dagger \) defined by eq. (10).

### 7.3 Demigrated reflection-time second derivatives

Assuming that the output point \((\mathbf{h}, \hat{\mathbf{x}}, T^X)\) from kinematic time demigration is known, one can map the second derivatives \( \mathbf{M} \rightarrow \mathbf{M}^\dagger \) by the following set of equations,

\[
\mathbf{M}^\dagger = u \mathbf{M}^h + \mathbf{L}^h - (u \mathbf{M}^h + \mathbf{L}^h - \mathbf{K}^h) (u \mathbf{M}^m - \mathbf{Y})^{-1} \times (u \mathbf{M}^m + \mathbf{L}^m - \mathbf{K}^m)^T,
\]

\[
\mathbf{M}^{x\dagger} = \mathbf{K}^h - (u \mathbf{M}^m + \mathbf{L}^m - \mathbf{K}^m) \times (u \mathbf{M}^m - \mathbf{Y})^{-1} (\mathbf{K}^m - \mathbf{U}^m)^T,
\]

\[
\mathbf{M}^{x\dagger h} = \mathbf{U}^m - (\mathbf{K}^m - \mathbf{U}^m) (u \mathbf{M}^m - \mathbf{Y})^{-1} (\mathbf{K}^m - \mathbf{U}^m)^T.
\]

For derivation, we refer to the reader to the second subsection of Appendix B. The mapping relations (46)–(48) include a number of auxiliary 2 × 2 matrices, defined in terms of diffraction-time partial derivatives (eq. 10) and reflection-time slopes \( \mathbf{\psi} \) in the time-migration domain (eq. 34),

\[
\mathbf{K}^h = \mathbf{U}^h + \mathbf{\psi} T^X, \quad \mathbf{K}^m = \mathbf{U}^m + u \mathbf{\psi}^m T^X. \quad \mathbf{L}^h = \mathbf{U}^h + \mathbf{\psi} T^X + u \mathbf{\psi}^m T^X + u T^X \mathbf{\psi}^h T^X, \quad \mathbf{L}^m = \mathbf{U}^m + \mathbf{\psi} T^X + u \mathbf{\psi}^m T^X + u T^X \mathbf{\psi}^m T^X, \quad \mathbf{L}^{x\dagger m} = \mathbf{U}^m + \mathbf{\psi}^m T^X + u T^X \mathbf{\psi}^m T^X,
\]

and also the matrix

\[
\mathbf{Y} = \mathbf{K}^m + \mathbf{K}^h T^X - (\mathbf{U}^m + \mathbf{U}^h).
\]

Among these, the matrices \( \mathbf{L}^{x\dagger m}, \mathbf{L}^h \) and \( \mathbf{Y} \) are symmetric.

Concerning physical interpretation of eqs (46)–(48), additional insight is provided from the second duality theorem in Kirchhoff depth migration (Schleicher et al. 2007, p. 159). This theorem relates second-order travelt ime derivatives corresponding to reflection (\( \mathbf{M}^\dagger \)) and diffraction (\( \mathbf{U}^m \)), at the location \((\mathbf{h}, \mathbf{x})\) of the recording domain, to curvatures of the reflector and the diffraction isochron, at the point \( D \) in the depth-migration domain (see Fig. 5). Eq. (48) can be viewed as the time-migration counterpart of the (depth-migration) second duality theorem in Schleicher et al. (2007). In the context of time migration, the matrices \( \mathbf{M}^{x\dagger m} \) and \( \mathbf{Y} \) can thus be interpreted, respectively, in terms of curvatures of the reflector and the diffraction isochron.

To first order, the change in the output position \( \hat{\mathbf{x}} \) can be described as

\[
\Delta \hat{\mathbf{x}} = \mathbf{X}^h \Delta \mathbf{h} + \mathbf{X}^m \Delta \mathbf{m},
\]

with 2 × 2 matrices \( \mathbf{X}^h \) and \( \mathbf{X}^m \) given by

\[
\mathbf{X}^h = \frac{\partial \hat{\mathbf{x}}}{\partial \Delta \mathbf{h}} = \left( \frac{\partial \hat{\mathbf{x}}}{\partial \mathbf{h}} \right), \quad \mathbf{X}^m = \frac{\partial \hat{\mathbf{x}}}{\partial \Delta \mathbf{m}} = \left( \frac{\partial \hat{\mathbf{x}}}{\partial \mathbf{m}} \right).
\]

The matrices \( \mathbf{X}^h \) and \( \mathbf{X}^m \) are characterizing the mapping of position coordinates performed by the time-demigration process. Moreover, \( \mathbf{X}^h \) and \( \mathbf{X}^m \) have similarities with paraxial (spreading) matrices known from ray theory. For these reasons, we refer to them as ‘time-demigration spreading matrices’. Considering a specific reflection event, \( \mathbf{X}^h \) and \( \mathbf{X}^m \) describe first-order changes of the 

### 7.4 Kinematic demigration from focused migrated images

If the time migration of the seismic data resulted in perfect focusing (no residual moveout after the migration), all derivatives of the migrated reflection time \( T \) with respect to half offset are zero. As a consequence, the matrices in eq. (49) are subjected to simplifications

\[
\mathbf{K}^h = \mathbf{U}^h, \quad \mathbf{L}^h = \mathbf{U}^h, \quad \mathbf{L}^{x\dagger h} = \mathbf{U}^m + u \mathbf{\psi}^m T^X,
\]

while eqs (45)–(47) and (54) reappear in idealized versions as

\[
\mathbf{p}^\dagger = \mathbf{q}^\dagger,
\]

\[
\mathbf{M}^\dagger = \mathbf{U}^h - (\mathbf{U}^m - \mathbf{U}^h + u \mathbf{\psi}^m T^X) (u \mathbf{M}^{x\dagger m} - \mathbf{Y})^{-1} \times (\mathbf{U}^m - \mathbf{U}^h + u \mathbf{\psi}^m T^X)^T, \quad \mathbf{M}^{x\dagger h} = (\mathbf{K}^h - (\mathbf{K}^m + \mathbf{L}^m - \mathbf{K}^m)^T (\mathbf{K}^m - \mathbf{U}^m)^T
\]

\[
\mathbf{X}^h = - (\mathbf{K}^m - \mathbf{U}^m)^T (\mathbf{U}^m - \mathbf{U}^h + u \mathbf{\psi}^m T^X)^T
\]
In eq. (57), the vector $p^k$ represents the reflection slope at half-offset $h$ within a CMP gather of time-demigrated seismic data at the location $x$. The matrix $M^{hk}$ in eq. (58) yields the associated (time) ‘curvature’ of the NMO function within that gather. We observe that the slopes of the diffraction time and the reflection time with respect to $h$ are equal. But this occurs only if the original time migration gave zero residual moveout.

### 7.5 Demigration at zero offset

In the zero-offset situation the diffraction-time partial derivatives satisfy eq. (14), while the reflection-time function $T$ exhibits the properties in eq. (30). This yields $u^h = 0$, $q^h = 0$, $p^h = 0$, and also $U^{ha} = U^{bh} = O, M^{xh} = O$. Using eq. (45) it follows that

$$\psi^h = 0. \quad (61)$$

In other words, at zero offset in the migration domain the slope of the reflection-time function is zero, regardless of the type of diffraction-time function and the parameterization of the time-migration velocity model. A further consequence is that $K^{xh} = L^{xh} = O$, and from eqs (46), (47) and (54) we therefore obtain

$$\mathcal{M}^{xh} = O. \quad (62)$$

$$X^h = O, \quad (63)$$

$$M^{xh} = u \mathcal{M}^{xh} + U^{xh}. \quad (64)$$

For a perfectly focused migration result at zero offset, we have $\mathcal{M}^{xh} = O$, so eq. (64) simplifies to

$$M^{xh} = U^{xh}. \quad (65)$$

Eq. (65) states that the second derivatives of reflection and diffraction time with respect to $h$ are equal for $h = 0$, a property known as the NIP-wave theorem (Chernyak & Gritsenko 1979; Hubral & Krey 1980). In the framework of second-order approximations this means that the traveltimes along the reflected and diffracted ray trajectories in Fig. 6, $SDR$ and $SDR$, can be considered equal.

### 8 KINEMATIC TIME MIGRATION

Our approach to kinematic migration is structured in a similar way as the kinematic demigration approach described above. A schematic overview is depicted in Fig. 4. The input reflection-time parameters to kinematic migration are exactly those that were output from kinematic demigration, namely, the time function $T$ and its first- and second-derivative parameters in eq. (27). These parameters are assumed known for a certain trace location $(h, x)$ in the recording domain. However, since the time-migration velocity model is specified in the migration domain, not in the recording domain, the partial derivatives of the diffraction-time function $T^p$ are inherently expressed in terms of the output point $(h, m, r)$ of the kinematic migration and not the input point, $(h, x, t)$. In order to solve this fundamental problem, it is necessary to compute the output point before proceeding to kinematic mapping of first- and second-order reflection-time parameters. Apart from trivial situations (e.g. assuming homogeneous time-migration velocity and single-square-root diffraction time) the computation of the output point will have to be done numerically.

In a kinematic migration corresponding to a reflection-time branch $T(h, x)$ in the recording domain the output trace location $(h, m)$ is assumed to have a single-valued relationship to the input trace location $(h, x)$ such that

$$m = \hat{m}(h, x). \quad (66)$$

The aperture function $\hat{a}$ introduced in eq. (38) is redefined accordingly to read

$$a = \hat{a}(h, x) = x - \hat{m}(h, x). \quad (67)$$

The migration output location, $\hat{m}$, will generally have to be found numerically, while the mapping of all first and second-derivative parameters can be performed by means of explicit formulas. For kinematic migration under the assumption of perfect focusing the mapping equations involving half-offset are the same as for kinematic demigration, see eqs (56)–(60) and (65).

### 8.1 Migrated position, reflection time, and reflection slopes

The basic conditions in eqs (41)–(42) formulated for kinematic demigration have to be satisfied also for kinematic migration. Hence, the output time $\hat{t}$ and the corresponding aperture vector $\hat{a}$ have to comply with the relations

$$\hat{T}(h, x) = T^D(h, \hat{a}, x - \hat{a}, \hat{t}), \quad (68)$$

$$\frac{\partial T}{\partial \hat{x}}(h, x) = T^D(h, \hat{a}, x - \hat{a}, \hat{t}). \quad (69)$$

The latter system of three component equations can be worked on iteratively until one finds a solution for $\hat{t}$ and $\hat{a}$ (and therefore also $\hat{m} = x - \hat{a}$). Thereby, we are ready to compute all the diffraction-time partial derivatives in eq. (10). The sought reflection time in the migration domain is retrieved as the solution $T^M = \hat{t}$.

From eqs (44) and (45) it is clear that slopes $\psi^h$ in the time-migration domain can be computed from slopes $\hat{p}$ in the recording domain using

$$\psi^h = \frac{1}{u}(p^h - q^h), \quad \hat{p}^m = \frac{1}{u}(p^h - q^h). \quad (70)$$
Knowing the slopes \( \hat{\Psi} \), and the diffraction-time partial derivatives in eq. (10), we have sufficient information to compute all the auxiliary \( 2 \times 2 \) matrices in eq. (49) and the matrix \( Y \) in eq. (50).

### 8.2 Migrated reflection-time second derivatives

The next step is to map reflection-time second derivatives \( \mathbf{m} \rightarrow \mathbf{M} \) from the recording domain to the time-migration domain. We achieve this by reversing the transformations in eqs (46)–(48) and taking advantage of intermediate results in Appendix B. This yields

\[
\mathbf{M}^{hh} = \frac{1}{n} \left[ \mathbf{M}^{hh} - \mathbf{L}^{hh} \right] - \left( \mathbf{M}^{kx} - \mathbf{K}^{kh} \right) \left( \mathbf{M}^{kx} - \mathbf{U}^{kx} \right)^{-1} \left( \mathbf{M}^{kx} - \mathbf{K}^{kh} \right)^T
\]

\[
\mathbf{M}^{hm} = \frac{1}{n} \left[ \mathbf{L}^{hm} - \mathbf{K}^{hm} + \left( \mathbf{M}^{kx} - \mathbf{K}^{hm} \right) \right] \times \left( \mathbf{M}^{kx} - \mathbf{U}^{kx} \right)^{-1} \left( \mathbf{K}^{hm} - \mathbf{U}^{hm} \right)
\]

\[
\mathbf{M}^{mm} = \frac{1}{n} \left[ \mathbf{Y} - \left( \mathbf{K}^{hm} - \mathbf{U}^{hm} \right)^2 \left( \mathbf{M}^{kx} - \mathbf{U}^{kx} \right)^{-1} \left( \mathbf{K}^{hm} - \mathbf{U}^{hm} \right) \right]
\]

(71)

For a particular reflection event, the change of output position \( \mathbf{m} \) is given to first order by

\[
\Delta \mathbf{m} = \mathbf{X}^h \Delta \mathbf{h} + \mathbf{X}^c \Delta \mathbf{x}
\]

(72)

where the two \( 2 \times 2 \) 'time-migration spreading matrices' \( \mathbf{X}^h \) and \( \mathbf{X}^c \) have the definitions

\[
\mathbf{X}^h = \frac{\partial \hat{\mathbf{m}}}{\partial \hat{\mathbf{h}}} = \left( \frac{\partial \mathbf{\hat{m}}}{\partial \mathbf{h}_j} \right), \quad \mathbf{X}^c = \frac{\partial \hat{\mathbf{m}}}{\partial \mathbf{x}} = \left( \frac{\partial \mathbf{\hat{m}}}{\partial \mathbf{x}_j} \right)
\]

(73)

The matrices \( \mathbf{X}^h \) and \( \mathbf{X}^c \) describe first-order changes of the common-image point as a result of changing, respectively, the half-offset vector and the CMP location, while the other entity (midpoint and half offset) is kept constant. The first-order change of the output trace location in the time-migration domain, \( \mathbf{\hat{m}} \), relative to the input trace location in the recording domain, \( \mathbf{\hat{x}} \), is

\[
\Delta \mathbf{\hat{m}} = \begin{pmatrix} 1 & 0 \\ \mathbf{X}^h & \mathbf{X}^c \end{pmatrix} \Delta \mathbf{\hat{x}}
\]

(74)

In view of eqs (53) and (74) the time-migration spreading matrices \( \mathbf{X}^h \) and \( \mathbf{X}^c \) can be expressed in terms of the corresponding time-demigration spreading matrices as

\[
\mathbf{X}^h = -\left( \mathbf{X}^w \right)^{-1} \mathbf{X}^h, \quad \mathbf{X}^c = \left( \mathbf{X}^w \right)^{-1}.
\]

(75)

Using eqs (54), (55), (75) and Appendix B, we formulate the time-migration spreading matrices in terms of reflection-time parameters of the recording domain as

\[
\mathbf{X}^h = \left( \mathbf{K}^{hm} - \mathbf{U}^{hm} \right)^{-1} \left( \mathbf{M}^{kx} - \mathbf{K}^{kh} \right)^T, \quad \mathbf{X}^c = \left( \mathbf{K}^{hm} - \mathbf{U}^{hm} \right)^{-1} \left( \mathbf{M}^{kx} - \mathbf{U}^{hm} \right).
\]

(76)

### 9 KINEMATIC TIME MIGRATION/DEMIGRATION USING SINGLE-/DOUBLE-SQUARE-ROOT DIFFRACTION TIMES

Up to now, we have considered completely general schemes for kinematic time migration and demigration, which are independent of the choice of diffraction-time function and the parametrization of the time-migration velocity model. In the following, we turn to considering kinematic migration/demigration with specific conventionally used functions, namely, the single and double square-root approximations. For the double-square-root approximation at arbitrary offsets (eq. 21), it is not practical to write explicit expressions for the mapping operations, as these will become very extensive. Instead, we refer to the general mapping framework described above, where one should insert diffraction-time partial derivatives as specified in Appendix C.

#### 9.1 Migration/demigration with single-square-root diffraction time

We consider kinematic migration an demigration using the single-square-root approximation to diffraction time (eq. 23). All required partial derivatives for this function are given in Appendix D.

#### Position and reflection time

Inserting the expressions for the partial derivatives given by eqs (D2), (D3) and (D4) into the consistency eq. (43) we obtain the relation

\[
4S_{ij} \hat{a}_i - T_M \psi^w - 2 \left( \frac{\partial S_{ij}^M}{\partial m_k} + \psi^w \frac{\partial S_{ij}^M}{\partial \tau} \right) (\hat{a}_i \hat{a}_j + h_i h_j) = 0.
\]

(77)

Eq. (77) can be used for demigration of the lateral input position \( \mathbf{m} \) in the time-migration domain, by finding the aperture vector \( \mathbf{\hat{a}} \) that corresponds to the time \( T_M \) and slope \( \psi^w \) of a reflection event identified in this domain. We observe that the equation is second order with respect to the components of vector \( \mathbf{\hat{a}} \), which implies two potential roots. One of these is to be classified as ‘non-physical’. If the variations of matrix \( S^M \) with \( (\mathbf{m}, \tau) \) are neglected one obtains the solution

\[
\hat{a} = \frac{1}{4} T_M S^{M^{-1}} \psi^w.
\]

(78)

The latter result, pertaining to a homogeneous time-migration velocity model, corresponds to Whiteside’s (1994) eq. (3) in the 2-D situation and to Soellner & Andersen’s (2005) eq. (8) in the 3-D situation. When vector \( \mathbf{\hat{a}} \) is known we use eq. (23) to obtain the demigrated reflection time, \( T^X \).

For kinematic migration it is generally required to solve the equation system (68)–(69), thus implying a simultaneous estimation of aperture vector \( \mathbf{\hat{a}} \) and migrated reflection time, \( T^M \). However, if the time-migration velocity model is homogeneous one can first compute \( \mathbf{\hat{a}} \) by combining eqs (69) and (D2) and subsequently the migrated time \( T^M \) using eq. (23).

#### Reflection-time slopes and second derivatives; spreading matrices

Having obtained the aperture vector \( \mathbf{\hat{a}} \) and the output (migrated/demigrated) reflection time, it is fairly straightforward to obtain all corresponding output slopes and second derivatives, by combining the above general formulations of kinematic migration/demigration with the explicit partial derivatives for the single-square-root diffraction-time function given in Appendix D.

For better insight and clarity, it may be instructive to neglect variations of matrix \( S^M \) with \( (\mathbf{m}, \tau) \). As a result, we get simple relations
\( T^X \mathbf{p}^* = T^M \psi^h + 4S^M \mathbf{h}, \)  
\( T^X \mathbf{p}^* = T^M \psi^w, \)  
\( T^X \mathbf{p}^* = T^M \psi^w + T^X \mathbf{h} + T^X \mathbf{M}, \)  
\( X^w = (84) \) may be computed by eq. (80). Alternatively, it can be obtained by combining eqs (42) and (D2), which yields \( \mathbf{p}^* = \frac{4}{T^X} S^M \hat{\mathbf{a}}. \)  
\( \mathbf{p}^* = \frac{4}{T^X} S^M \hat{\mathbf{a}}. \)  
\( \mathbf{p}^* = \frac{4}{T^X} S^M \hat{\mathbf{a}}. \)  
\( \mathbf{p}^* = \frac{4}{T^X} S^M \hat{\mathbf{a}}. \)  
\( \mathbf{p}^* = \frac{4}{T^X} S^M \hat{\mathbf{a}}. \)  
\( \mathbf{p}^* = \frac{4}{T^X} S^M \hat{\mathbf{a}}. \)  
\( \mathbf{p}^* = \frac{4}{T^X} S^M \hat{\mathbf{a}}. \)  
\( \mathbf{p}^* = \frac{4}{T^X} S^M \hat{\mathbf{a}}. \)  
\( \mathbf{p}^* = \frac{4}{T^X} S^M \hat{\mathbf{a}}. \)  
\( \mathbf{p}^* = \frac{4}{T^X} S^M \hat{\mathbf{a}}. \)  
\( \mathbf{p}^* = \frac{4}{T^X} S^M \hat{\mathbf{a}}. \)
Figure 7. Example 1: 2-D depth model with five homogeneous isotropic layers (indices 1–5) and four interfaces (indices 1–4). The constant layer velocities are, from top to bottom, 1.5, 1.8, 2.1, 2.15 and 2.4 km s$^{-1}$. Reflection rays for the source point at horizontal location 7.0 km are superimposed. [Correction made after online publication 2012 April 26: the labelling in this figure has been corrected.]

Figure 8. Example 1: reflection events simulated by ray tracing from 241 source points in the 2-D model (Fig. 7). Zero-offset gather (top panel) and common-midpoint gathers (bottom panel) corresponding to the locations 3.0, 6.0 and 9.0 km. The modulus of the half-offset vector is the horizontal coordinate of the common-midpoint gathers.
and 21 in combination). Let us further assume that for a given location \( x \) and zero offset, \( h = 0 \), the reflection time \( T_x \), the slope vector \( p_x \), and the NMO matrix, \( S_{NMO} \), are known. Estimation of the latter from seismic data requires that observations are available for at least three different directions of the half-offset vector. A corresponding time-migration matrix, \( \hat{S}_M \), can then be estimated using eq. (84), but we do not yet know its location \( (\hat{m}, \hat{\tau}) \). For that, we can first use eq. (83), which applies to both the single- and double-square-root functions at zero offset, to obtain the aperture vector \( \hat{a} \) and then the image-gather location \( \hat{m} = x - \hat{a} \). Thereafter, we use eq. (23) with \( h = 0 \) to compute the migration time, \( \hat{\tau} \).

Having applied this direct estimation procedure to yield a number of samples \( (\hat{m}, \hat{\tau}, \hat{S}_M) \), the function \( S_M(m, \tau) \) is finally established by regularization.

11 NUMERICAL EXAMPLES

The methodology presented above is illustrated by means of two numerical examples.

11.1 Example 1

Consider a 2-D depth model with five homogeneous isotropic layers (Fig. 7) separated by four interfaces. Layers and interfaces are numbered sequentially from top to bottom by indices 1-5 and 1-4, respectively. Interfaces 1 and 2 are planar and dipping, interface 3 has significant undulations, while interface 4 is planar and horizontal. The constant velocities in layers 1 through 5 are 1.5, 1.8, 2.1, 2.15 and 2.4 km s\(^{-1}\). The velocity contrast across interface 3 is on purpose chosen to be very small, to avoid distorting the kinematic time migration corresponding to interface 4.

For each interface we simulated reflection events corresponding to a marine seismic survey with sources located at zero depth and between the horizontal locations 1.0 and 13.0 km. The source separation is 50 m (241 source points in total). The events were ‘recorded’ along a 4.0 km long towed receiver cable with receiver separation 50 m (81 receiver positions for each source point). Each simulated event is characterized by the following (minimum) information: the half-offset component, \( h_1 \), the midpoint coordinate, \( x \), and the migration time, \( \tau \).
the reflection time, $T_X$, and the reflection slope, $p_1$. A subset of the simulated reflection times is shown in Fig. 8. We observe that interface 3 gives rise to multiple arrivals.

The generated event data were pretended to be our seismic observations and we mapped them to the time-migration domain using the presented procedure for kinematic time migration. The inherent diffraction time was represented by the standard double-square root function (eqs 17 and 21). To start with the required time-migration velocity model was not known, so as a rough initial guess we let the time-migration velocity be constant and equal to 1.6 km s$^{-1}$. This corresponds to a squared time-migration slowness $S_{M11} = 0.390625$ s$^2$ km$^{-2}$. Fig. 9 shows the reflection events after kinematic time migration using this homogeneous time-migration velocity model. In the upper subfigure all mapped events have been projected into the zero-offset section, while the three lower subfigures shows common-image gathers of the events at the horizontal locations 3.0, 6.0 and 9.0 km. Using these types of plots one can get a first indication of whether the time-migrated image will be well focused or not. It is obvious that our chosen initial time-migration velocity model is quite inadequate, in the sense that the events appear with significant residual moveout. Also, the triplications of the reflections from interface 3 have not been completely unfolded. On the other hand, the initial time-migration model is of sufficient quality to permit the identification of adequate single-valued reflection-time surfaces over most of the half-offset/image-gather area (Fig. 10).

From the reflection-time surfaces in Fig. 10 we estimated the reflection-time parameter $\mathcal{M}_{11}$ at zero offset. This would correspond to applying a standard velocity analysis procedure (Taner & Koehler 1969) to common-image gathers of pre-stack time-migrated seismic data. In this way, we replaced the velocity analysis/event picking step (that would have to be included in the presence of real seismic data) with a surface fitting operation.

Having obtained the parameter $\mathcal{M}_{11}$ we performed a kinematic time demigration at zero offset, which yielded the corresponding reflection-time parameter $M_{h11}^T$ (eq. 64) and therefore also the squared NMO slowness, $S_{NMO11}$ (eq. 31). Knowing this entity, we took advantage of eq. (84) to estimate the corresponding squared time-migration slowness, $S_{M11}^T$, and its associated image-gather and migration-time coordinates. After applying regularization and smoothing in these coordinates we obtained the updated result for $S_{M11}^T$ given in Fig. 11(a). The corresponding time-migration velocity is shown in Fig. 11(b).

Using the updated time-migration velocity model we applied again kinematic time migration to the full set of ‘recorded’ events. The result (Fig. 12) is to be compared to the one obtained using

Figure 10. Example 1: reflection surfaces in the time-migration domain established from kinematically time-migrated events (Fig. 9). The vertical separation between contours is 25 ms.
the initial homogeneous model (Fig. 9). For the two upper reflection surfaces there is still some residual moveout, but this appears only at very large offsets. The reason is probably a combination of errors introduced in the estimation of the parameter $M_{11}^{hh}$, the regularization/smoothing procedure, and by the fact that diffraction times for interface 2 at very large offsets do not comply well with the standard double-square root function. For the two lowermost reflection surfaces one can observe a striking improvement of the imaging of the interface geometry as well as of the event flatness in common-image gathers. In a real data processing situation the
Figure 12. Example 1: reflection events after kinematic time migration using the updated $S_{11}$ field in Fig. 11(a). Projection of events for all offsets into the zero-offset section (top panel) and common-image gathers (bottom panel) for the same locations as in Fig. 9.

far-offset shallow reflections are commonly muted. To be consistent with this practice we also applied a simple mute function to the reflection events before performing the kinematic time migration process. After these operations the ‘image’ of all four reflectors appears very well focused (Fig. 13).

As a final comment to example 1, observe that interface 4 is not imaged as exactly planar horizontal in the time-migration domain. This is an intrinsic effect of time migration which cannot be repaired by improving the time-migration velocity model.

11.2 Example 2

In example 1 the velocity contrast across interface 3 was very small, and kinematic time migration with respect to the reflections from interface 4 gave a nicely focused result. As a natural follow-up, we wanted to obtain a corresponding result in the situation where a larger velocity contrast appears across interface 3. We achieved this by introducing a linearly and laterally varying velocity function with a quite strong gradient, 0.1 s$^{-1}$, in layer 4 while the velocity at horizontal distance 0 km was the same as before, 2.15 km s$^{-1}$. For an impression of this modified model, see Fig. 14. As in Fig. 7 some ray paths are superimposed, but now only those corresponding to reflections at interface 4. The increasing velocity contrast along interface 3 is seen to yield significant focusing effects.

New reflection event data were generated for interface 4 (Fig. 15) and regularized data for the function $S_{11}$ (see Fig. 16) were re-estimated by the same procedure as before. Using the updated $S_{11}$, the whole event data set was muted and thereafter kinematically migrated (Fig. 17).

We find the result in Fig. 17 very encouraging. The greater velocity contrast at interface 3 makes it difficult to estimate a consistent $S_{11}$ in two regions with strong focusing effects. These regions are located below the troughs of interface 3 appearing approximately at the horizontal locations 2.5 and 6 km. The ‘image’ of interface 4 in these regions is observed to be somewhat more blurry than in example 1 (Fig. 13) but is by no means completely distorted.
Figure 13. Example 1: reflection events after kinematic time migration as in Fig. 12, but with mute applied to the input events.

Figure 14. Example 2: modified 2-D depth model including a horizontal velocity gradient 0.1 s$^{-1}$ in layer 4. Reflection rays for the source point at horizontal location 7.0 km and interface 4 are superimposed. For comparison with the original model, see Fig. 7. [Correction made after online publication 2012 April 26: the labelling in this figure has been corrected.]
Furthermore, the result for interface 4 is characterized by typical pull-up and pull-down effects caused by strong lateral velocity variations in the overburden.

12 CONCLUSIONS

We present a generalization of kinematic time migration and demigration for arbitrary, constant, source-receiver offsets. The description is developed beyond mapping of reflection times and slopes, including also reflection curvatures. Local heterogeneity of the time-migration velocity model is accounted for, and the derived mapping equations do not depend specifically on the type of diffraction-time function and the parametrization of the velocity model. One fundamental requirement is that the diffraction-time field does not contain caustics. This ensures that the mapping between the time-migration domain and the depth-migration domain, which may be accomplished using image rays, is one-to-one. In this way, the results tie in with earlier work on estimating geological dips and curvatures from time-migrated zero-offset reflections.

The established mapping framework opens for interesting observations and interpretations. Mapping of reflection curvature in time-migration common-image coordinates to reflection curvature in CMP coordinates (or vice versa) represents the time-migration counterpart of the second duality theorem in Kirchhoff depth migration. We also show that the NIP-wave theorem follows naturally from the basic conditions involved in kinematic time migration and demigration. As a byproduct of the mapping operations we obtain time-migration and time-demigration spreading matrices, which have similarities with paraxial matrices known from ray theory. Regardless of the time-migration velocity model, some of the reflection-time parameters in the time-migration domain are always zero at zero offset, namely, the reflection-time slope with respect to offset and the reflection-time mixed second derivatives (with respect to offset and common-image coordinates).

We consider two specific examples of diffraction-time functions for time migration and demigration, namely, the classic single- and double-square-root functions. The single-square root function has limited applicability (offsets and apertures must be small) and is studied here because of its attention in the past and the simplicity of...

REFERENCES

In the context of single-scattering based seismic imaging, the notion of propagation of singularities coincides essentially with map migration and demigration using, respectively, the slopes in the data and the dips in the reflectivity or image. For a historical overview, see the introduction of Douma & de Hoop (2006). In the following, propagation of singularities is utilized in the context of time migration and demigration: in time migration one generates time-migrated data \( d^M(h, m, \tau) \) from recorded data \( d(h, x, t) \); in time demigration one transforms \( d^M(h, m, \tau) \) back to the recording domain, resulting in the time-demigrated data \( \tilde{d}(h, x, t) \).

The extended time-demigration operator, \( F^* \), associated with eq. (7) can be written in the form \( \tilde{d}(h, x, t) = (FD^M)(h, x, t) \), where

\[
\tilde{d}(h, x, t) = \iiint W(h, x, m, \tau, \omega) \exp[i\phi(h, x, t, m, \tau, \omega)] \times d^M(h, m, \tau) \, dm \, dt \, d\omega, \tag{A1}
\]

with phase function

\[
\phi(h, x, t, m, \tau, \omega) = \omega [T^D(h, x - m, m, \tau) - t] \tag{A2}
\]

and frequency-dependent weight function \( W(h, x, m, \tau, \omega) \). In principle, \( W \) can be derived from the Born approximation and asymptotic ray theory, while \( d^M \) can be related to reflectivity using image-ray coordinates. Details concerning how \( W \) can be estimated are, however, outside the scope of this paper. Eq. (8) outlines that \( W \) can be connected with a frequency-independent weight function similar to the one used by Schleicher et al. (2007, p. 195, eq. 5).

The extended time-migration operator, \( F^* \), is obtained by taking the adjoint of \( F \). The time-migrated data can then be expressed as

\[
d^M(h, m, \tau) = \iiint W^*(h, x, m, \tau, \omega) \exp[-i\phi(h, x, t, m, \tau, \omega)] \times d(h, x, t) \, dx \, dt \, d\omega
= \iiint W^*(h, m + a, m, \tau, \omega) \times \exp[-i\phi(h, m + a, t, m, \tau, \omega)] \times d(h, m + a, t) \, da \, dt \, d\omega, \tag{A3}
\]

introducing (relative) aperture coordinates, \( a = x - m \). Corrections to the amplitude of \( F^* \) are obtained upon considering the composition \( FF^* \) and constructing its asymptotic inverse. The operator \( F \) is the time demigration analogue of the surface-offset extension of the single scattering operator considered by Stolk et al. (2009). In the absence of caustics, operator \( F \) is asymptotically invertible.

The propagation of singularities by the operator \( F \) follows from evaluating the set of points,

\[
\left\{ h, x, t, \frac{\partial \phi}{\partial h}, \frac{\partial \phi}{\partial x}, \frac{\partial \phi}{\partial t}, \frac{\partial \phi}{\partial m}, -\frac{\partial \phi}{\partial \tau}, \frac{\partial \phi}{\partial \omega} \right\} \quad \text{at} \quad \frac{\partial \phi}{\partial \omega} = 0, \tag{A4}
\]

signifying the stationary point set, and is described by the so-called canonical relation (Grigis & Sjöstrand 1994)

\[
\Lambda_\phi = \left\{ h, x, T^D(h, x - m, m, \tau), \omega \frac{\partial T^D}{\partial h}(h, x - m, m, \tau), \frac{\omega}{\partial \omega}(-h, x - m, m, \tau), -\omega; \right. \nonumber
h, m, \tau, -\omega \frac{\partial T^D}{\partial h}(h, x - m, m, \tau), \left. -\omega \frac{\partial T^D}{\partial m}(h, x - m, m, \tau), -\omega \frac{\partial T^D}{\partial \tau}(h, x - m, m, \tau) \right\}. \tag{A5}
\]

The propagation of singularities reads that \( (h, x, t, p^x, p^t, \omega) \) belongs to the wavefront set of the recorded or time-demigrated seismic data (i.e. corresponds with an event) if there exists \( (h, m, \tau, \psi^h, \psi^m, v) \) such that \( (h, x, t, p^x, p^t, \omega, h, m, \tau, \psi^h, \psi^m, v) \) belongs to \( \Lambda_\phi \) and \( (h, m, \tau, \psi^h, \psi^m, v) \) is contained in the wavefront of the extended time-migrated image. The scalar \( v \) can be interpreted as a frequency variable associated with the time-migration domain. In fact, \( \Lambda_\phi \) is the graph of an invertible transformation, \( \Theta \), which prescribes the propagation of singularities. We note that \( h \) plays the role of a parameter; it is constant under the application of the transformation \( \Theta \).

In eq. (A5), \( \partial T^D/\partial \tau \) signifies the ‘coordinate stretch’ between migration time and recording time; it is the quantity \( u \) defined in eq. (10). For the corresponding coordinate stretch between migration depth and recording time, see, for example, Tygel et al. (1994).

If the singular support of the extended time-migrated image can be described (locally) by a level set function \( T \), that is, \( \tau = T(h, m) \), one can define a time-demigration map from \( (h, m) \) to \( x \), through a projection of the elements of the wavefront set obtained from \( [h, m, T(h, m), -\partial T(h, m)/\partial h, -\partial T(h, m)/\partial m, 1] \) using the canonical relation; in the main text this map is denoted by \( \hat{x} \). The singular support of the time-demigrated data can be correspondingly described (locally) by a level set function \( T \), that is, \( t = T(h, x) \), so that

\[
T(h, \hat{x}(h, m)) = T^D(h, \hat{x}(h, m) - m, m, T(h, m)); \tag{A6}
\]

moreover, the dual to \( x \) in the canonical relation gives the correspondence

\[
\hat{a}T \frac{\partial T}{\partial x}[h, \hat{x}(h, m)] = \hat{a}T \frac{\partial T}{\partial h}[h, \hat{x}(h, m) - m, m, T(h, m)]. \tag{A7}
\]

Eqs (A6)–(A7) coincide with eqs (41)–(42).

The propagation of singularities by time migration is straightforwardly described by \( \Lambda^* \). The singular support of the recorded data and the extended time-migrated image then correspond, respectively, to the level set functions \( t = T(h, x) \) and \( \tau = T(h, m) \). One defines a time-migration map from \( (h, x) \) to \( m \) through a projection of the elements of the wavefront set of the extended image obtained from \( [h, x, T(h, x), \delta T(h, x)/\delta h, \delta T(h, x)/\delta m, -1] \); in the main text this map is denoted by \( \hat{m} \). This yields

\[
T(h, x) = T^D(h, x - \hat{m}(h, x), \hat{m}(h, x), T[h, \hat{m}(h, x)] \tag{A8}
\]

according to the canonical relation (A5).

**APPENDIX B: TRANSFORMATIONS BETWEEN DERIVATIVES OF REFLECTION TIME IN THE MIGRATION AND RECORDING DOMAINS**

The topic of this appendix is derivation of transformations between derivatives of reflection time in the migration and recording domains, both being considered in their common-offset representations.

**B1 First-order partial derivatives**

Consider first eq. (38). Differentiation with respect to half-offset coordinates \( h_i \) and position components \( m_k \) in the time-migration domain yields

\[
\frac{\partial \hat{a}_i}{\partial h_i} = \frac{\partial \hat{a}_i}{\partial h_i}, \tag{B1}
\]
\[
\begin{align*}
\frac{\partial a_i}{\partial m_i} &= \frac{\partial \tilde{x}_i}{\partial m_i} - \delta_{ia}.
\end{align*}
\] (B2)

Now we take derivatives of the basic condition in eq. (41) with respect to position components \(m_i\). The result is
\[
\frac{\partial \tilde{x}_i}{\partial m_i} = \frac{\partial T^D}{\partial m_i} + \frac{\partial T}{\partial m_i} \frac{\partial T^D}{\partial \tau} + \frac{\partial \tilde{a}_i}{\partial m_i} \frac{\partial T^D}{\partial \tau}.
\] (B3)

In the last equation we recognize the components, \(\partial \tilde{x}_i/\partial m_i\), of the time-demigration spreading matrix \(X^m\) (eq. 52). Using eqs (42) and (B2) in eq. (B3) yields
\[
\frac{\partial T}{\partial \tau} = \frac{\partial T^D}{\partial m_i} + \frac{\partial T}{\partial m_i} \frac{\partial T^D}{\partial \tau}.
\] (B4)

This equation relates the first derivatives of reflection time \(\partial T/\partial m_i\) and \(\partial T/\partial \tau\). Using eq. (42) in eq. (B4) results in the so-called consistency equation,
\[
\frac{\partial T^D}{\partial a_i} = \frac{\partial T}{\partial m_i} \frac{\partial T^D}{\partial \tau}.
\] (B5)

It is given as eq. (43) in the main text.

Differentiation of eq. (41) with respect to half-offset components \(h_i\) yields
\[
\frac{\partial \tilde{x}_i}{\partial h_i} = \frac{\partial T^D}{\partial h_i} + \frac{\partial T}{\partial h_i} \frac{\partial T^D}{\partial \tau} + \frac{\partial \tilde{a}_i}{\partial h_i} \frac{\partial T^D}{\partial \tau}.
\] (B6)

Applying eq. (B1) and the basic condition (42), we find that the derivatives \(\partial T/\partial h_i\) and \(\partial T/\partial \tau\) are related by the equation
\[
\frac{\partial T}{\partial \tau} = \frac{\partial T^D}{\partial h_i} + \frac{\partial T}{\partial h_i} \frac{\partial T^D}{\partial \tau}.
\] (B7)

B2 Second-order partial derivatives
The basic condition in eq. (42) is differentiated with respect to coordinates \(m_i\) to yield
\[
\frac{\partial \tilde{x}_i}{\partial m_i} = \frac{\partial T^D}{\partial m_i} + \frac{\partial T}{\partial m_i} \frac{\partial T^D}{\partial \tau} + \frac{\partial \tilde{a}_i}{\partial m_i} \frac{\partial T^D}{\partial \tau}.
\] (B8)

We also differentiate eq. (B4) with respect to \(m_i\), which gives
\[
\frac{\partial \tilde{x}_i}{\partial m_i} = \frac{\partial T}{\partial m_i} \frac{\partial \tilde{x}_i}{\partial \tau} + \frac{\partial T}{\partial m_i} \frac{\partial T^D}{\partial \tau} + \frac{\partial \tilde{a}_i}{\partial m_i} \frac{\partial T^D}{\partial \tau} + \frac{\partial T^D}{\partial \tau} \left(\frac{\partial \tilde{a}_i}{\partial m_i} \frac{\partial \tilde{x}_i}{\partial \tau}ight).
\] (B9)

Using that the right-hand sides of eqs (B8) and (B9) have to be equal, and also taking into account eq. (B2), we obtain
\[
\frac{\partial \tilde{x}_i}{\partial m_i} = \frac{\partial \tilde{x}_i}{\partial \tau} \frac{\partial T^D}{\partial \tau} + \frac{\partial T}{\partial m_i} \frac{\partial \tilde{x}_i}{\partial \tau} + \frac{\partial \tilde{a}_i}{\partial m_i} \frac{\partial \tilde{x}_i}{\partial \tau} + \frac{\partial T}{\partial m_i} \frac{\partial T^D}{\partial \tau} + \frac{\partial \tilde{a}_i}{\partial m_i} \frac{\partial T^D}{\partial \tau} + \frac{\partial \tilde{a}_i}{\partial m_i} \frac{\partial \tilde{x}_i}{\partial \tau}.
\] (B10)

Using the definitions in eq. (11) and (49), the equivalent matrix form of eq. (B10) is
\[
-(K^{m^*} - U^{m^*})^T X^m = u M^{m^*} - Y.
\] (B11)

Eq. (B11) can be used for computation of the time-demigration spreading matrix \(X^m\), the final expression for it is given in eq. (55).

A minor rearrangement of terms in eq. (B8) yields
\[
\left(\frac{\partial^2 T}{\partial x_i \partial x_j} - \frac{\partial^2 T^D}{\partial a_i \partial a_j}\right) \frac{\partial \tilde{x}_i}{\partial m_i} = \frac{\partial^2 T}{\partial a_i \partial m_i} \frac{\partial T^D}{\partial \tau} + \frac{\partial \tilde{a}_i}{\partial m_i} \frac{\partial T^D}{\partial \tau}.
\] (B12)

or in matrix form,
\[
(M^{m^*} - U^{m^*}) X^m = K^{m^*} - U^{m^*}.
\] (B13)

By combining eqs (B11) and (B13) matrix \(X^m\) is eliminated, and we obtain the explicit formula for matrix \(M^{m^*}\) in eq. (48).

Our next task is to find an expression for the mixed-term second-derivative matrix belonging to the recording domain, \(M^h = (\partial^2 T/\partial h_i \partial \tau)\). We proceed by differentiating eq. (B7) with respect to \(m_i\),
\[
\frac{\partial \tilde{x}_i}{\partial h_i} = \frac{\partial^2 T}{\partial h_i \partial m_i} + \frac{\partial T}{\partial h_i} \frac{\partial \tilde{x}_i}{\partial \tau} + \frac{\partial \tilde{a}_i}{\partial h_i} \frac{\partial \tilde{x}_i}{\partial \tau} + \frac{\partial T}{\partial h_i} \frac{\partial T^D}{\partial \tau} + \frac{\partial \tilde{a}_i}{\partial h_i} \frac{\partial T^D}{\partial \tau} + \frac{\partial \tilde{a}_i}{\partial h_i} \frac{\partial \tilde{x}_i}{\partial \tau}.
\] (B14)

which can be restated as
\[
\begin{align*}
&\left(\frac{\partial^2 T}{\partial h_i \partial x_j} - \frac{\partial^2 T}{\partial a_i \partial a_j}\right) \frac{\partial \tilde{x}_i}{\partial m_i} = \frac{\partial^2 T}{\partial a_i \partial m_i} \frac{\partial T^D}{\partial \tau} + \frac{\partial \tilde{a}_i}{\partial m_i} \frac{\partial T^D}{\partial \tau} \left(\frac{\partial \tilde{a}_i}{\partial a_i} \frac{\partial \tilde{x}_i}{\partial \tau}\right) + \frac{\partial T}{\partial h_i} \frac{\partial \tilde{x}_i}{\partial m_i} + \frac{\partial T}{\partial a_i} \frac{\partial \tilde{x}_i}{\partial m_i} + \frac{\partial \tilde{a}_i}{\partial a_i} \frac{\partial \tilde{x}_i}{\partial m_i}.
\end{align*}
\] (B15)

Applying the definitions in eq. (11) and (49), we rewrite eq. (B15) in matrix form as follows,
\[
(M^{h^*} - K^{h^*}) X^m = u M^{h^*} + L^{h^*} - K^{h^*}.
\] (B16)

Combination of the last result with eq. (B11) eliminates matrix \(X^m\) and yields eq. (47) for matrix \(M^{h^*}\).

Differentiation of eq. (42) with respect to half-offset component \(h_i\) gives
\[
\frac{\partial \tilde{x}_i}{\partial h_i} = \frac{\partial \tilde{x}_i}{\partial \tau} \frac{\partial T^D}{\partial \tau} + \frac{\partial T}{\partial h_i} \frac{\partial \tilde{x}_i}{\partial \tau} + \frac{\partial \tilde{a}_i}{\partial h_i} \frac{\partial \tilde{x}_i}{\partial \tau} + \frac{\partial T}{\partial h_i} \frac{\partial T^D}{\partial \tau} + \frac{\partial \tilde{a}_i}{\partial h_i} \frac{\partial T^D}{\partial \tau} + \frac{\partial \tilde{a}_i}{\partial h_i} \frac{\partial \tilde{x}_i}{\partial \tau}.
\] (B17)

which can be rewritten as
\[
\begin{align*}
&\left(\frac{\partial^2 T}{\partial x_i \partial x_j} - \frac{\partial^2 T}{\partial a_i \partial a_j}\right) \frac{\partial \tilde{x}_i}{\partial h_i} = -\frac{\partial^2 T}{\partial a_i \partial h_i} \frac{\partial \tilde{x}_i}{\partial h_i} + \frac{\partial^2 T}{\partial a_i \partial h_i} \frac{\partial T^D}{\partial \tau} + \frac{\partial \tilde{a}_i}{\partial h_i} \frac{\partial T^D}{\partial \tau}.
\end{align*}
\] (B18)

with the corresponding matrix form
\[
(M^{h^*} - U^{h^*}) X^h = -(M^{h^*} - K^{h^*})^T.
\] (B19)

We observe that the time-demigration spreading matrix \(X^h\) (see eq. 52) can be determined from eq. (B19). Utilizing also the relations (47)–(48) leads to eq. (54), which relates matrix \(X^h\) solely to
diffraction-time partial derivatives and reflection-time parameters belonging to the time-migration domain.

To obtain the second-derivative matrix $\mathbf{M}^{hh} = (\partial^2 T / \partial h_1 \partial h_2)$, we differentiate eq. (B7) with respect to $h_1$,

$$
\frac{\partial^2 T}{\partial h_1 \partial h_2} + \frac{\partial^2 T}{\partial h_1 \partial h_2} + \frac{\partial^2 T}{\partial h_1 \partial h_2} + \frac{\partial^2 T}{\partial h_1 \partial h_2} + \frac{\partial^2 T}{\partial h_1 \partial h_2}
$$

which can be restated as

$$
\frac{\partial^2 T}{\partial h_1 \partial h_2} + \frac{\partial^2 T}{\partial h_1 \partial h_2} + \frac{\partial^2 T}{\partial h_1 \partial h_2} + \frac{\partial^2 T}{\partial h_1 \partial h_2} + \frac{\partial^2 T}{\partial h_1 \partial h_2}
$$

or equivalently,

$$
\mathbf{M}^{hh} = u \mathbf{M}^h + L^{hh} - (\mathbf{M}^{hv} - \mathbf{K}^{hv}) \mathbf{X}^h. \quad \text{(B22)}
$$

Taking into account eq. (B16) and already derived time-demigration spreading matrices in eqs (54)–(55), we obtain the formula for matrix $\mathbf{M}^{1h}$ in eq. (46).

**APPENDIX C: PARTIAL DERIVATIVES OF THE DOUBLE-SQUARE-ROOT FUNCTION**

The double-square-root function is given by the combination of eq. (5) with eq. (21). In this appendix we specify all its partial derivatives up to second order.

**C1 First-order partial derivatives**

$$
\frac{\partial T^S}{\partial h_1} = -\frac{1}{T^S} S_{S1}^M(a_j - h_j),
$$

$$
\frac{\partial T^R}{\partial h_1} = \frac{1}{T^R} S_{S1}^M(a_j + h_j), \quad \text{(C1)}
$$

$$
\frac{\partial T^S}{\partial a_1} = \frac{1}{T^S} S_{S1}^M(a_j - h_j),
$$

$$
\frac{\partial T^R}{\partial a_1} = \frac{1}{T^R} S_{S1}^M(a_j + h_j), \quad \text{(C2)}
$$

$$
\frac{\partial T^S}{\partial m_1} = \frac{1}{2T^S} S_{S1}^M(a_j - h_j)(a_j - h_j),
$$

$$
\frac{\partial T^R}{\partial m_1} = \frac{1}{2T^R} S_{S1}^M(a_j + h_j)(a_j + h_j), \quad \text{(C3)}
$$

$$
\frac{\partial T^S}{\partial \tau} = \frac{1}{T^S} \left[ \frac{\tau}{4} + \frac{3}{2} \frac{\partial S^M_{S1}}{\partial \tau}(a_j - h_j)(a_j - h_j) \right],
$$

$$
\frac{\partial T^R}{\partial \tau} = \frac{1}{T^R} \left[ \frac{\tau}{4} + \frac{3}{2} \frac{\partial S^M_{S1}}{\partial \tau}(a_j + h_j)(a_j + h_j) \right] \quad \text{(C4)}
$$

**C2 Second-order partial derivatives**

$$
\frac{\partial^2 T^S}{\partial h_1 \partial h_1} = \frac{1}{T^S} \left( S_{S1}^M - \frac{\partial T^S}{\partial h_1} \frac{\partial T^S}{\partial h_1} \right),
$$

$$
\frac{\partial^2 T^R}{\partial h_1 \partial h_1} = \frac{1}{T^R} \left( S_{S1}^M - \frac{\partial T^R}{\partial h_1} \frac{\partial T^R}{\partial h_1} \right), \quad \text{(C5)}
$$

$$
\frac{\partial^2 T^S}{\partial a_1 \partial a_1} = \frac{1}{T^S} \left( S_{S1}^M - \frac{\partial T^S}{\partial a_1} \frac{\partial T^S}{\partial a_1} \right),
$$

$$
\frac{\partial^2 T^R}{\partial a_1 \partial a_1} = \frac{1}{T^R} \left( S_{S1}^M - \frac{\partial T^R}{\partial a_1} \frac{\partial T^R}{\partial a_1} \right), \quad \text{(C6)}
$$

$$
\frac{\partial^2 T^S}{\partial m_1 \partial m_1} = \frac{1}{T^S} \left[ \frac{1}{2} \frac{\partial S^M_{S1}}{\partial m_1}(a_j - h_j)(a_j - h_j) - \frac{\partial T^S}{\partial m_1} \frac{\partial T^S}{\partial m_1} \right],
$$

$$
\frac{\partial^2 T^R}{\partial m_1 \partial m_1} = \frac{1}{T^R} \left[ \frac{1}{2} \frac{\partial S^M_{S1}}{\partial m_1}(a_j + h_j)(a_j + h_j) - \frac{\partial T^R}{\partial m_1} \frac{\partial T^R}{\partial m_1} \right], \quad \text{(C7)}
$$

$$
\frac{\partial^2 T^S}{\partial h_1 \partial m_1} = -\frac{1}{T^S} \left[ \frac{\partial S^M_{S1}}{\partial m_1}(a_j - h_j) + \frac{\partial T^S}{\partial h_1} \frac{\partial T^S}{\partial m_1} \right],
$$

$$
\frac{\partial^2 T^R}{\partial h_1 \partial m_1} = \frac{1}{T^R} \left[ \frac{\partial S^M_{S1}}{\partial m_1}(a_j + h_j) - \frac{\partial T^R}{\partial h_1} \frac{\partial T^R}{\partial m_1} \right], \quad \text{(C8)}
$$

$$
\frac{\partial^2 T^S}{\partial a_1 \partial m_1} = \frac{1}{T^S} \left[ \frac{\partial S^M_{S1}}{\partial m_1}(a_j - h_j) - \frac{\partial T^S}{\partial a_1} \frac{\partial T^S}{\partial m_1} \right],
$$

$$
\frac{\partial^2 T^R}{\partial a_1 \partial m_1} = \frac{1}{T^R} \left[ \frac{\partial S^M_{S1}}{\partial m_1}(a_j + h_j) - \frac{\partial T^R}{\partial a_1} \frac{\partial T^R}{\partial m_1} \right], \quad \text{(C9)}
$$

$$
\frac{\partial^2 T^S}{\partial m_1 \partial \tau} = -\frac{1}{T^S} \left[ \frac{\partial S^M_{S1}}{\partial \tau}(a_j - h_j) + \frac{\partial T^S}{\partial m_1} \frac{\partial T^S}{\partial \tau} \right],
$$

$$
\frac{\partial^2 T^R}{\partial m_1 \partial \tau} = \frac{1}{T^R} \left[ \frac{\partial S^M_{S1}}{\partial \tau}(a_j + h_j) - \frac{\partial T^R}{\partial m_1} \frac{\partial T^R}{\partial \tau} \right], \quad \text{(C10)}
$$

$$
\frac{\partial^2 T^S}{\partial h_1 \partial \tau} = -\frac{1}{T^S} \left[ \frac{\partial S^M_{S1}}{\partial \tau}(a_j - h_j) + \frac{\partial T^S}{\partial h_1} \frac{\partial T^S}{\partial \tau} \right],
$$

$$
\frac{\partial^2 T^R}{\partial h_1 \partial \tau} = \frac{1}{T^R} \left[ \frac{\partial S^M_{S1}}{\partial \tau}(a_j + h_j) - \frac{\partial T^R}{\partial h_1} \frac{\partial T^R}{\partial \tau} \right], \quad \text{(C11)}
$$

$$
\frac{\partial^2 T^S}{\partial a_1 \partial \tau} = \frac{1}{T^S} \left[ \frac{\partial S^M_{S1}}{\partial \tau}(a_j - h_j) - \frac{\partial T^S}{\partial a_1} \frac{\partial T^S}{\partial \tau} \right],
$$

$$
\frac{\partial^2 T^R}{\partial a_1 \partial \tau} = \frac{1}{T^R} \left[ \frac{\partial S^M_{S1}}{\partial \tau}(a_j + h_j) - \frac{\partial T^R}{\partial a_1} \frac{\partial T^R}{\partial \tau} \right], \quad \text{(C12)}
$$

$$
\frac{\partial^2 T^S}{\partial m_1 \partial \tau} = \frac{1}{T^S} \left[ \frac{\partial S^M_{S1}}{\partial \tau}(a_j - h_j) + \frac{\partial T^S}{\partial m_1} \frac{\partial T^S}{\partial \tau} \right],
$$

$$
\frac{\partial^2 T^R}{\partial m_1 \partial \tau} = \frac{1}{T^R} \left[ \frac{\partial S^M_{S1}}{\partial \tau}(a_j + h_j) + \frac{\partial T^R}{\partial m_1} \frac{\partial T^R}{\partial \tau} \right], \quad \text{(C13)}
$$

Geophysical Journal International © 2012 RAS
\[ \frac{\partial^2 T^S}{\partial \tau^2} = \frac{1}{T^2} \left[ \frac{1}{4} + \frac{1}{2} \frac{\partial^2 S^M_{ij} (a_i, a_j)}{\partial T^D \partial \tau} (a_i - h_i)(a_j - h_j) - \left( \frac{\partial T^S}{\partial \tau} \right)^2 \right]. \]
\[ \frac{\partial^2 T^R}{\partial \tau^2} = \frac{1}{T^2} \left[ \frac{1}{4} + \frac{1}{2} \frac{\partial^2 S^M_{ij} (a_i, a_j)}{\partial T^D \partial \tau} (a_i + h_i)(a_j + h_j) - \left( \frac{\partial T^R}{\partial \tau} \right)^2 \right]. \]

(C14)

**APPENDIX D: PARTIAL DERIVATIVES OF THE SINGLE-SQUARE-ROOT FUNCTION**

The single-square-root function, see eq. (23), has first- and second order partial derivatives as specified in the following.

**D1 First-order partial derivatives**

\[ q^h_k = \frac{\partial T^D}{\partial h_k} = \frac{4}{T^D} S^M_{ij} h_j, \]

(D1)
\[ q^e_k = \frac{\partial T^D}{\partial a_i} = \frac{4}{T^D} S^M_{ij} a_j, \]

(D2)
\[ q^m_k = \frac{\partial T^D}{\partial m_k} = \frac{2}{T^D} \frac{\partial S^M_{ij}}{\partial m_k} (a_i a_j + h_i h_j), \]

(D3)
\[ u = \frac{\partial T^D}{\partial \tau} = \frac{1}{T^D} \left[ \frac{\partial S^M_{ij}}{\partial \tau} (a_i a_j + h_i h_j) \right]. \]

(D4)

**D2 Second-order partial derivatives**

\[ U^{jh}_{kl} = \frac{\partial^2 T^D}{\partial h_k \partial h_l} = \frac{1}{T^D} \left( 4 S^M_{ij} - \frac{\partial T^D}{\partial h_i} \frac{\partial T^D}{\partial h_j} \right). \]

(D5)
\[ U^{ja}_{kl} = \frac{\partial^2 T^D}{\partial a_i \partial a_l} = \frac{1}{T^D} \left( 4 S^M_{ij} - \frac{\partial T^D}{\partial a_i} \frac{\partial T^D}{\partial a_j} \right), \]

(D6)
\[ U^{jm}_{kl} = \frac{\partial^2 T^D}{\partial m_k \partial m_l} = \frac{1}{T^D} \left[ \frac{\partial^2 S^M_{ij}}{\partial m_k \partial m_l} (a_i a_j + h_i h_j) - \frac{\partial T^D}{\partial m_k} \frac{\partial T^D}{\partial m_l} \right], \]

(D7)
\[ U^{ha}_{kl} = \frac{\partial^2 T^D}{\partial h_k \partial a_l} = - \frac{1}{T^D} \frac{\partial T^D}{\partial h_k} \frac{\partial T^D}{\partial a_l}, \]

(D8)
\[ U^{ja}_{kl} = \frac{\partial^2 T^D}{\partial a_i \partial m_l} = \frac{1}{T^D} \left( 4 S^M_{ij} - \frac{\partial T^D}{\partial a_i} \frac{\partial T^D}{\partial m_j} \right). \]

(D9)
\[ U^{jm}_{kl} = \frac{\partial^2 T^D}{\partial m_k \partial a_l} = \frac{1}{T^D} \left( 4 S^M_{ij} - \frac{\partial T^D}{\partial m_i} \frac{\partial T^D}{\partial a_j} \right). \]

(D10)
\[ u^h = \frac{\partial^2 T^D}{\partial h_k \partial \tau} = \frac{1}{T^D} \left( 4 \frac{\partial S^M_{ij}}{\partial \tau} h_j - \frac{\partial T^D}{\partial h_k} \frac{\partial T^D}{\partial \tau} \right), \]

(D11)
\[ u^m = \frac{\partial^2 T^D}{\partial m_k \partial \tau} = \frac{1}{T^D} \left( 4 \frac{\partial S^M_{ij}}{\partial \tau} a_j - \frac{\partial T^D}{\partial m_k} \frac{\partial T^D}{\partial \tau} \right). \]

(D12)

**APPENDIX E: PARTIAL DERIVATIVES OF THE SINGLE/DUPLICATE SQUARE-ROOT FUNCTION AT ZERO OFFSET**

At zero offset, the first and second derivatives of the single and duplicate square-root forms of the diffraction-time function are identical, with one important exception. When using the double-square-root form we obtain

\[ U^{jh}_{ij} = \frac{\partial^2 T^D}{\partial h_i \partial h_j} = \frac{1}{T^D} \left( 4 S^M_{ij} - \frac{\partial T^D}{\partial a_i} \frac{\partial T^D}{\partial a_j} \right), \]

(E1)

while the corresponding relation for the single-square-root function is

\[ U^{jh}_{ij} = \frac{\partial^2 T^D}{\partial h_i \partial h_j} = \frac{4}{T^D} S^M_{ij}. \]

(E2)

Relations for the remaining derivatives, which are identical to the two representations in the zero-offset situation, are listed in the following.

**E1 First-order partial derivatives**

\[ q^h_k = \frac{\partial T^D}{\partial h_k} = 0. \]

(E3)
\[ q^e_k = \frac{\partial T^D}{\partial a_i} = \frac{4}{T^D} S^M_{ij} a_j, \]

(E4)
\[ q^m_k = \frac{\partial T^D}{\partial m_k} = \frac{2}{T^D} \frac{\partial S^M_{ij}}{\partial m_k} a_i a_j, \]

(E5)
\[ u = \frac{\partial T^D}{\partial \tau} = \frac{1}{T^D} \left( \frac{\partial S^M_{ij}}{\partial \tau} a_i a_j \right). \]

(E6)

**E2 Second-order partial derivatives**

\[ U^{jh}_{ij} = \frac{\partial^2 T^D}{\partial a_i \partial a_j} = \frac{1}{T^D} \left( 4 S^M_{ij} - \frac{\partial T^D}{\partial a_i} \frac{\partial T^D}{\partial a_j} \right). \]

(E7)
\[ U^{jm}_{ij} = \frac{\partial^2 T^D}{\partial m_i \partial a_j} = \frac{1}{T^D} \left( 2 \frac{\partial S^M_{ij}}{\partial m_i} a_i a_j - \frac{\partial T^D}{\partial m_i} \frac{\partial T^D}{\partial a_j} \right). \]

(E8)
\[ U^{ja}_{ij} = \frac{\partial^2 T^D}{\partial a_i \partial m_j} = \frac{1}{T^D} \left( 4 S^M_{ij} - \frac{\partial T^D}{\partial a_i} \frac{\partial T^D}{\partial m_j} \right). \]

(E9)
