Abstract

In many environments, professionals have miscalibrated beliefs about their skills and knowledge, which potentially compromises the quality of their work. Why might a firm be better off hiring an individual known to be over- or under-confident? In this paper, I argue that such biases can alleviate agency frictions. I present a model in which an agent uses his private information to make a choice on behalf of a principal. Players differ in their preferred action in a given state of the world. In this setting, I consider what I call the belief design problem: how would the principal like the agent to interpret his private information? I provide conditions under which the solution to this problem can be interpreted as the principal preferring a rational, an under-confident, or an over-confident agent. Rationality is strictly preferred by the principal if and only if the expected difference in the players’ preferred actions does not vary with the signal realization.

Keywords: principal-agent, overconfidence, organizational design, belief design

*I am deeply thankful with David Besanko, Luis Rayo, Daniel Barron, and Wojciech Olszewski for their advice and encouragement. I would also like to thank Henrique Castro-Pires, Théo Durandard, Benjamin Golub, Edwin Muñoz-Rodriguez, Michael Powell, Bruno Strulovici, Alvaro Sandroni, Jeroen Swinkels, Boli Xu, and Gabriel Ziegler for their insightful comments and suggestions.

†Kellogg School of Management - Northwestern University. Email: andres.espitia@kellogg.northwestern.edu.
1 Introduction

There is extensive evidence about the pervasiveness of overconfidence (Malmendier and Taylor, 2015). CEOs, executives, and managers (Malmendier and Tate, 2005; Ben-David et al., 2013; Adam et al., 2015; Barrero, 2021); traders and investors (Daniel and Hirshleifer, 2015); lawyers (Goodman-Delahunty et al., 2010); medical doctors (Berner and Graber, 2008; Croskerry and Norman, 2008); and entrepreneurs (Koellinger et al., 2007) have all been found to exhibit some degree of overconfidence.

Moreover, overconfidence can severely compromise the quality of employees’ decisions, destroying firms’ value. In the words of Nobel laureate Daniel Kahneman, “an unbiased appreciation of uncertainty is a cornerstone of rationality – but it is not what people and organizations want” (see Kahneman, 2011, chap. 24).1 Given the costs that organizations suffer due to overconfidence, why might employees known to be overconfident be systematically hired and retained, even when rational counterparts are available? Additionally, how would organizations use their knowledge about applicants’ confidence to select their employees optimally?

In this paper, I explore the role of biased beliefs as an instrument to alleviate agency frictions (those arising from different preferences among the members of the organization). In this exercise, I entirely focus on a particular manifestation of overconfidence: overprecision – an exaggerated faith in one’s information. Informally speaking, individuals suffer from overprecision whenever they think that they are more informed than they actually are. Intuitively, an overconfident employee is desired by the firm when his rational counterpart is too unresponsive to new information.2 Overprecision leads to more extreme responses to private information. This overreaction helps the firm, for example, when employees would otherwise stay too close to some reference action.

In order to examine the implications of this mechanism, I develop a model in which an employee makes a decision that affects both himself and the firm. While there is disagreement about the right course of action, the employee has private access to relevant but unverifiable information. In this setting, I introduce a novel feature: the firm can choose how the employee interprets his observations. I refer to this decision by the firm as the belief design problem.

---

1Furthermore, “Kahneman recently told an interviewer that if he had a magic wand that could eliminate one human bias, he would do away with overconfidence” (Malmendier and Taylor, 2015, pg. 1).

2Other forms of overconfidence include overestimation (thinking that one’s performance and abilities are above their actual level) and overplacement (erroneously thinking that one has outperformed others or that one’s abilities are above those of other individuals).
Formally, belief design corresponds to an optimization problem in which the firm chooses the employee’s posterior beliefs after each signal realization, subject to the constraint that players agree ex-ante on the distribution of the state and signals. In practice, it can be understood as a process in which the firm selects employees with the desired beliefs among a pool of candidates with sufficiently diverse views of the world. I focus on how the employee interprets information exogenously produced. This is in contrast with the information design approach (see Kamenica, 2019) which focuses on the actual provision of information to the employee.

The contributions of this paper are threefold. First, the main contribution is to provide specific conditions under which the firm prefers a rational, underconfident, or overconfident employee, which I discuss below. The second contribution corresponds to the methodology used to establish these conditions. Belief design is a flexible and tractable approach to study belief-based biases. A crucial step is to interpret the beliefs optimally chosen by the firm. I propose a definition of overprecision based on a stochastic order that applies to a general class of information structures.\(^3\) Third, I study the interaction between belief design and other tools that the firm could use to mitigate the costs of agency frictions. In particular, I allow the firm to commit to action-contingent transfers. I also consider the possibility of centralizing decision making.

A central object to describe the optimal employee’s characteristics is the difference in the actions preferred by each player in each state, which I refer to as the conflict of interests. Since the employee is ex-ante well-calibrated, his actions will be biased on average. Under the standard assumption of quadratic-loss preferences, the firm dislikes changes in the employee’s actions that are not justified by his private information. The optimal employee (i.e. the one with beliefs that solve the belief design problem) agrees with the firm on the responses to his information, i.e., the average bias on his actions is evenly distributed across signal realizations. As a result, the firm prefers a rational employee if and only if the expected conflict of interest is invariant in the signal realization (first part of Proposition 1, generalized in Proposition 2).

In contrast, if the signal affects the expected conflict of interest evenly distributing the employee’s bias requires that the optimal employee takes lower actions than his rational counterpart after signal realizations that induce high expected conflict of interests. The critical condition for the optimality of overconfidence is that the signal moves the conditional expectation of the

\(^3\)The standard approach would be to assume a particular joint distribution and restrict biased-beliefs to belong to the same parametric family. Two commonly assumed structures are the bi-variate normal distribution and the truth-or-noise (in which the signal reveals the states with a certain probability and it is noise otherwise). This last case is discussed in Appendix B.
conflict of interests and the employee’s preferred action in opposite directions (second part of Proposition 1 and Proposition 3). If this is the case, the optimal agent takes more extreme actions than the rational one, which is a manifestation of overconfidence. Analogously, an underconfident employee is optimal if the expected conflict of interests and the employee’s preferred action move in the same direction.

Optimality of overconfidence arises in situations in which, for example, the employee’s preferred action increases less than proportionally than the firm’s preferred action. This may occur because it is costly for the employee to adjust to the current conditions or because he is subject to some degree of status quo bias. Thus, the demand for overconfidence may arise as a strategy to mitigate the effects of other pervasive behavioral biases, status quo bias in decision-making being a salient example.

Additionally, I explore the effect of other tools that organizations may use to mitigate the effects of agency frictions. First, I study the interaction between belief design and action-contingent transfers. I discuss conditions under which the use of transfers does not change the optimal beliefs (Proposition 4). Moreover, in the optimum, these tools are used for different purposes: beliefs are used to spread the employee’s bias across signal realizations, while transfers are used to decrease his average bias. Interestingly, belief design leads to “flatter” compensation contracts: all equilibrium actions taken by the optimal employee yield the same transfer. In contrast, when the employee is restricted to be rational, the optimal transfers vary with the actions he takes in equilibrium.

Finally, while modeled symmetrically in this paper, overconfidence and underconfidence have a stark difference: there is a natural substitute for extreme underconfidence. Namely, the firm can make the choice without the information held by the employee. When the firm allocates decision rights to the employee, it is only with the hope of using his private information. When the optimal employee is not sufficiently confident, the firm is better off avoiding the conflict of interests altogether by centralizing decision-making (Proposition 5).

**Related literature**

The interest in the economic effects of overconfidence is long-standing. The term, however,

---

4 It is sometimes assumed that adjustment costs are paid by the firm (see Barrero, 2021). Absent any additional frictions, my results support the conclusion that any deviation from rationality would be detrimental for the firm.

5 For example, Adam Smith stated that “the overweening conceit which the greater part of men have of their own abilities, is an ancient evil remarked by the philosophers and moralists of all ages” (Smith, 1776, chap. X, book I).
has been used to describe quite distinct phenomena (see Moore and Healy, 2008). In this paper I entirely focus on overprecision, which is considered the most robust and least understood form of overconfidence (Haran et al., 2010; Moore and Schatz, 2017).

This paper provides a simple framework to study the effects of overconfidence in organizations. The results link the demand for overconfidence to the joint behavior of the preferences of the members of the organization. Previous studies have described some potential benefits of overconfidence (broadly defined), which can be classified roughly into three groups. First, overconfidence may serve as a strategic commitment device, allowing the firm or some of its members to implement strategies that would not otherwise be credible (see Kyle and Wang, 1997; Rotemberg and Saloner, 2000; Van den Steen, 2005; Gervais and Goldstein, 2007; Enghmaier, 2011; Bolton et al., 2013; Enghmaier and Reisinger, 2014; Phua et al., 2018; Ba and Gindin, 2020). Second, it may permit more favorable acquisition, revelation, and aggregation of private information (see Bernardo and Welch, 2001; Blanes i Vidal and Möller, 2007; Che and Kartik, 2009; Van den Steen, 2010; Levy and Razin, 2015; Ostrizek, 2019; Hestermann and Le Yaouanc, 2020). Finally, it may allow the firm to have better control over risk-taking and sharing as well as facilitating diversification (see Goel and Thakor, 2008; Santos-Pinto, 2008; De la Rosa, 2011; Gervais et al., 2011; Palomino and Sadrieh, 2011; Heller, 2014).

I illustrate how belief-based selection can be used as an indirect source of incentives. Numerous tools that organizations can use to deal with conflicting preferences have been studied. One possibility consists in exploiting individual characteristics to improve outcomes (Prendergast and Stole, 1996; Prendergast, 2007, 2008). I contribute to this literature by considering beliefs as part of those characteristics. On the other hand, the literature on information design (Rayo and Segal, 2010; Kamenica and Gentzkow, 2011; Kamenica, 2019) shares the same object of choice, but the focus is on the information that the employee would actually observe rather than on how he interprets the information that is exogenously available to him.

2 Model

Preliminaries

For any finite set $X \subset \mathbb{R}$, I use $\Delta(X)$ to denote the set of probability mass functions over $X$. Subscripts on operators are used explicitly indicate the specific probability mass function used, e.g., $E_g$ indicates that the expectation is taken according to the distribution $g \in \Delta(X)$. For any
joint distribution $g \in \Delta(X \times X')$, let $g_X \in \Delta(X)$ and $g_{X'} \in \Delta(X')$ denote its marginals. Finally, all variables with a tilde are random variables.

**Players and actions**

An agent (he) makes a decision $x \in \mathbb{R}$ that also affects a principal (she). Payoffs depend on an unknown state of the world $\theta \in \Theta := \{\theta_1, \ldots, \theta_n\} \subset \mathbb{R}$, with $n \geq 2$ finite. States are labeled such that $\theta_1 < \cdots < \theta_n$.

**Information**

The agent has private and non-verifiable information about the state of the world. He observes a signal realization $s \in S := \{s_1, \ldots, s_m\}$, with $m \geq 2$ finite. From the point of view of the principal, states and signals are distributed according to $f \in \Delta(\Theta \times S)$, which is an $n \times m$ matrix with $ij$-th entry equal to $f(\theta_i, s_j) = \text{Pr}_f[\tilde{\theta} = \theta_i, \tilde{s} = s_j]$. I refer to $f$ as the true distribution and assume full-support, i.e. $f(\theta, s) > 0$ for all $(\theta, s) \in \Theta \times S$. Higher states are more likely after higher signal realizations, in particular, signals are labeled such that $s_j = \mathbb{E}_f[\tilde{\theta} | \tilde{s} = s_j]$.

**Belief design**

The key feature of this model is that the principal is allowed to choose how the agent interprets his private information. This is, she chooses a distribution $g \in \Delta(\Theta \times S)$ such that after observing a given signal realization the agent posterior beliefs are computed according to $g$ instead than according to $f$. This step can be interpreted as a selection or hiring process in which the principal chooses an agent that already posses the desired beliefs. Alternatively, it can also reflect the principal’s ability to (costlessly) train the agent on how to interpret his information.\(^6\)

I impose two restrictions on the set of joint distributions the principal can select. First, I assume that players ex-ante agree on the distribution of the state, i.e. $g_\Theta = f_\Theta$. Additionally, I require the agent to be well-calibrated about the frequency of signal realizations, i.e. $g_S = f_S$. These restrictions allows us to focus on the information the agent perceives after each signal realization. Let $\mathcal{G} := \{g \in \Delta(\Theta \times S) : g_\Theta = f_\Theta, g_S = f_S\}$ denote the set of feasible choices for the principal.

**Timing and payoffs**

\(^6\)See Haran et al. (2010) and Meikle et al. (2016) for practices that can mitigate or exacerbate miscalibration.
The timing of events is as follows

1. Belief design: the principal chooses \( g \in \mathcal{G} \).

2. Nature draws \((\theta, s)\) according to \( f \).

3. The agent observes \( s \), interpreting it according to \( g \), and chooses \( x \in \mathbb{R} \).

Payoffs are given by \( -(x - \theta)^2 \) for the principal and by \( -(x - y(\theta))^2 \) for the agent. That is, the state is normalized to represent the principal’s preferred action. On the other hand, the agent’s preferred action is given by the bias function \( y : \Theta \rightarrow \mathbb{R} \). I assume that \( y \) is strictly increasing. This provides some minimum degree of alignment in the players’ preferences.

The difference between the players’ preferred actions in a given state will play an important role in the analysis. I denote it by \( c(\theta) := y(\theta) - \theta \) and refer to it as the conflict of interest in state \( \theta \).

Finally, note that the description of the timing assumes that the agent learns nothing from the principal’s choice. This is, interpreting belief design as a selection process, candidates’ beliefs remain the same whether they are selected by the principal or not. This assumption is supported by existing evidence about the persistence of overconfidence.

**Applications**

I now discuss two specific applications. The purpose is to illustrate the type of situations in which the forces captured by the model are relevant. We will revisit these applications to illustrate the implications of the results.

First, consider a CEO (the principal) selecting a middle manager (the agent) in charge of compensating a subordinate. Specifically, the manager chooses a level of reward \( x \in \mathbb{R} \) for his subordinate after having privately observed a signal of the subordinate’s actual performance. The state represents the CEO’s ideal level of reward given the subordinate’s actual performance, which is never directly observed. The signal is normalized to represent the CEO’s ideal level of reward given some noisy measure of the subordinate’s performance.

A plausible concern for the CEO is that the manager would be overly reluctant to provide low rewards to his subordinate. This is, while the two parties may be relatively aligned when the
subordinate deserves a bonus or a promotion, the manager may be averse to fire the subordinate, even when the CEO wants exactly that.

Second, consider the director of a nuclear power plant (the principal) selecting a risk manager (the agent) in charge of monitoring and controlling the safety in the plant’s operations. The manager chooses a level of risk abatement \( x \in \mathbb{R} \) after having privately observed a signal about the safety conditions of the operations. The state represents the director’s ideal abatement level given the actual performance of the plant. As in the previous application, the signal represents the director’s ideal abatement level given some noisy measure of the performance of the plant. In this case, both individuals would agree about the right course of action when the risk is high: avoiding an accident is a mutual goal when problems are likely to occur. On the other hand, when the risk is sufficiently low, the manager does not see the need to keep the abatement at the levels desired by the director.

In both contexts we ask the following question: when is an over/under-confident manager optimal? This question, however, is not entirely meaningful without a definition of overconfidence. This is precisely the next step.

**Defining overconfidence**

Our goal is to provide conditions under which the optimal agent displays beliefs that can be interpreted as over/under-confidence. If the optimal agent’s beliefs coincide with the ones prescribed by the true distribution \( f \), then we say that he is rational. Otherwise, we need to compare a given solution \( g^* \) with \( f \). I propose using a well-known stochastic order to make such comparisons in a way that reflects the notion of over/under-precision. This order is based on the concept of concordance, which informally corresponds to large values of the state going together with large values of the signal. Thus, an increase in the concordance between these two random variables can be interpreted as the signal “revealing more” about the state.

**Definition 1 (Concordance Order)** \( g \in \mathcal{G} \) dominates \( f \) in the concordance order, denoted \( g \succeq f \), if and only if for all \( k \in \{1, \ldots, n\} \) and \( l \in \{1, \ldots, m\} \) we have
\[
\sum_{i=1}^{k} \sum_{j=1}^{l} g(\theta_i, s_j) \geq \sum_{i=1}^{k} \sum_{j=1}^{l} f(\theta_i, s_j). \tag{7}
\]

The concordance order ranks two distributions by comparing their cumulative functions point-wise. When \( g \succeq f \), the probability that the realizations of the state and the signal are

---

both “small” is higher under $g$ than under $f$. Since $g$ and $f$ have the same marginals, it is also true that the probability that the realizations of the state and the signal are both high increases when their distribution change from $f$ to $g$ (Epstein and Tanny, 1980, theorem 3). Therefore, an agent with beliefs $g \succeq f$ interprets higher signal realization as stronger evidence of higher states than his rational counterpart. To the extent that overprecision is informally understood as an excessive faith in one’s information then this definition captures exactly that.  

Additionally, $g \succeq f$ implies that the (Pearson) correlation coefficient, the Kendall’s $\tau$, and the Spearman’s $\rho$ between the state and the signal are all higher under $g$ than under $f$ (Tchen, 1980). The converse is not true in general. Thus, the concordance order is more conservative than, for instance, comparing covariances as a criteria to define overprecision (which has the additional problem of lacking a strong justification beyond the multivariate-normal case).

Finally, note that we can have a distribution $g \preceq f$ that reverses the relationship among states and signal realizations, such that a high signal ends up being evidence of a low state. This extreme change in the interpretation of the signal is not compatible with the idea of overprecision. However, given the maintained assumptions, this problem does not arise in the current setting. In particular, $y(\cdot)$ being increasing guarantees that the solution to the belief design problem is always above (in the concordance order) the independent distribution, i.e., any solution $g^*$ satisfies $g^*(\theta, s) \geq f_\Theta(\theta)f_S(s)$ for all $(\theta, s)$.

Thus, if we find a solution $g^* \neq f$ with $g^* \succeq f$, we can say that the optimal agent is overconfident. Analogously, when $f \preceq g^*$ we can say that he is underconfident.

3 Analysis

For any $g \in \Delta(\Theta \times S)$ and signal realization $s \in S$, the agent optimally chooses $E_g[y(\tilde{\theta})|\tilde{s} = s]$. Note that all feasible beliefs yield the same average action:

\[
E_f \left[ E_g \left[ y(\tilde{\theta})|\tilde{s} = s \right] \right] = E_g \left[ E_g \left[ y(\tilde{\theta})|\tilde{s} = s \right] \right] = E_g \left[ y(\tilde{\theta}) \right] = E_f \left[ y(\tilde{\theta}) \right]
\]

where the first equality follows from $f_S = g_S$, the second from the law of iterated expectations, and the third from $g_\Theta = f_\Theta$.

\footnote{In the present two-dimensional setting other orders – the supermodular stochastic order, greater weak association, the convex-modular order, and the dispersion order – coincide with the concordance order (see Meyer and Strulovici, 2012).}
Knowing the agent’s actions, we can express the principal’s expected payoff as a function of any belief $g$ as $U(g) := -\mathbb{E} f \left[ \left( \mathbb{E}_g [y(\tilde{\theta}) | \tilde{s}] - \tilde{\theta} \right)^2 \right]$. As a result, belief design corresponds to the following optimization problem

$$\max_{g \in G} U(g).$$

I will divide the analysis of this problem into two parts. As a first step, I focus on the simplest version of the model, in which the state and signal spaces are binary. Then, I discuss the key insights that extend to the general version of the model. All proofs are provided in appendix A.

### 3.1 The $n = m = 2$ case

Assume that $n = m = 2$. The starting point is the set of feasible choices for the principal. Consider any deviation from the true distribution $f$. In particular, suppose we want to modify the probability of some pair of states and signals, say $(\theta_1, s_1)$, by adding some amount $\varepsilon \in \mathbb{R}$. Since marginal probabilities must remain constant, we need to adjust the probability of $(\theta_1, s_2)$ and $(\theta_2, s_1)$ by adding $-\varepsilon$. As a consequence, we also need to add $\varepsilon$ to the probability of $(\theta_2, s_2)$. This is, the change from the true distribution to any feasible distribution is fully described by a single scalar.$^9$ Formally, any $g \in G$ can decomposed as $f + \varepsilon B$ where $\varepsilon \in \mathbb{R}$ is a scalar and $B \in \mathbb{R}^{2 \times 2}$ is a matrix of constants.$^{10}$

Furthermore, $\varepsilon$ is constrained by the fact that the resulting $g$ must be a well-defined probability mass function, i.e. $g(\theta_i, s_j) \in [0, 1]$. Consequently, $\varepsilon$ must belong to some compact interval $[\underline{\varepsilon}, \bar{\varepsilon}]$. The full support assumption guarantees that $\underline{\varepsilon} < 0 < \bar{\varepsilon}$. This is, any marginal deviation from the true distribution is feasible.

As a result, the belief design problem can be seen as as choosing $\varepsilon \in [\underline{\varepsilon}, \bar{\varepsilon}]$ to maximize $U(f + \varepsilon B)$, which is a well-behaved concave maximization program. Before discussing its solu-

---

$^9$Some authors refer to the scalar $\varepsilon$ as an elementary transformation (see Epstein and Tanny, 1980).

$^{10}$Specifically, this decomposition can be seen as

$$g = \begin{bmatrix} f(\theta_1, s_1) + \varepsilon & f(\theta_1, s_2) - \varepsilon \\ f(\theta_2, s_1) - \varepsilon & f(\theta_2, s_2) + \varepsilon \end{bmatrix} = \begin{bmatrix} f(\theta_1, s_1) & f(\theta_1, s_2) \\ f(\theta_2, s_1) & f(\theta_2, s_2) \end{bmatrix} + \varepsilon \begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix} = f + \varepsilon B.$$

$^{11}$The bounds on the interval are as follows

$$\underline{\varepsilon} := -\min \{ f(\theta_1, s_1), 1 - f(\theta_1, s_2), 1 - f(\theta_2, s_1), f(\theta_2, s_2) \}$$

$$\bar{\varepsilon} := \min \{ 1 - f(\theta_1, s_1), f(\theta_1, s_2), f(\theta_2, s_1), 1 - f(\theta_2, s_2) \}.$$
tion, note that an increase in $\varepsilon$ corresponds to a shift in probability mass from the off-diagonal of $g$ to its diagonal. That is, the agent’s belief that the state is $\theta_i$ after observing $s_i$ increases with $\varepsilon$. Therefore, we can interpret $\varepsilon$ as the agent’s level of confidence: an agent with $\varepsilon > 0$ is overconfident, with $\varepsilon < 0$ is underconfident, and rational otherwise. This is both intuitive and consistent with the definition of overconfidence proposed in section 2.

Increasing $\varepsilon$ makes agent’s actions more extreme: as $\varepsilon$ grows the agent’s action after observing $s_i$ gets closer to $y(\theta_i)$. Equivalently, the agent’s action increases with $\varepsilon$ after $s_2$ and decreases after $s_1$. Therefore, increasing $\varepsilon$ benefits the principal when a rational agent would take too low actions after $s_2$ or too high actions after $s_1$, e.g. when $c(\theta_1) > c(\theta_2)$.

The following result describes the optimal agent in the $n = m = 2$ case. As the previous intuition suggested, the joint behavior of the agent’s preferred action, $y(\tilde{\theta})$, and the conflict of interests, $c(\tilde{\theta}) = y(\tilde{\theta}) - \tilde{\theta}$, plays a key role.

**Proposition 1** The unique optimal agent is

- **rational if and only if the conflict of interests and the agent’s preferred action are uncorrelated.**
- **overconfident if and only if the conflict of interests and the agent’s preferred action are negatively correlated.**
- **underconfident if and only if the conflict of interests and the agent’s preferred action are positively correlated.**

In this case, the conflict of interests and the agent’s preferred actions being uncorrelated is equivalent to a constant conflict of interests. Therefore, a rational agent is optimal if and only if his bias is additive, i.e. $y(\theta) = \theta + b$. This extends to the optimal agent too, he would ideally behave as if his bias was additive. However, the bounds on $\varepsilon$ may prevent the principal from getting that far.

The proof of proposition 1 shows that the interior optimum is given by

$$\varepsilon^* = -\frac{\text{Cov}_f(c(\tilde{\theta}), y(\tilde{\theta}))}{\text{Var}_f(y(\tilde{\theta}))}|f| = \left[\frac{\text{Cov}_f(c(\tilde{\theta}), y(\tilde{\theta}))}{\text{Var}_f(y(\tilde{\theta}))} - 1\right]|f|$$

where $|f|$ denotes the determinant of the matrix $f$. 

11
Since signal realizations are labeled by the conditional expectation over states they induce, it follows that $|f| > 0$. Assuming that $y(\cdot)$ is increasing directly implies that $\varepsilon^* > -|f| \in (\varepsilon, 0)$. This is, since an agent whose confidence equals $-|f|$ acts as if the signal was uninformative, the optimal agent always extract some information from the signal.

Moreover, the optimal confidence level increases with the slope of the best affine predictor of the principal’s preferred action, $\tilde{\theta}$, as a function of the agent’s preferred action, $y(\tilde{\theta})$. This slope formally captures the notion of agent’s unresponsiveness that overprecision can mitigate: whenever it is above one the optimal agent turns out to be overconfident. Lastly, if for given primitives we have $\varepsilon^* > \bar{\varepsilon}$ then the solution is $\bar{\varepsilon}$, i.e. the optimal agent is maximally overconfident.

Now I can illustrate the implications of the result for the applications described in section 2. First, the CEO concerns about the manager’s reluctance to punish his subordinate can be captured by assuming $y(\theta_1) > \theta_1$ and $y(\theta_2) \approx \theta_2$. It follows that $c(\theta_1) > c(\theta_2)$, and by proposition 1 we conclude that the CEO would strictly prefer to hire an overconfident manager.

On the other hand, in the nuclear power plant example, the friction is due to the manager’s low willingness to mitigate risks when an accident is unlikely to occur. This can be represented by assuming $y(\theta_1) < \theta_1$ and $y(\theta_2) \approx \theta_2$. It follows that $c(\theta_1) < c(\theta_2)$, and we conclude that the optimal risk manager would be underconfident.

### 3.2 General case

I this subsection, I lift the assumption on the number of states and signals. We start by observing that the objective function in the belief design problem can be decomposed as follows

$$U(g) = -E_f \left[ (E_f[\tilde{\theta}|s] - \tilde{\theta})^2 \right] - E_f \left[ c(\tilde{\theta}) \right]^2 - Var_f (E_g[y(\tilde{\theta})|s] - E_f[\tilde{\theta}|s]).$$

The first term represents the payoff that the principal could obtained if she was informed and choosing the action. It corresponds to a loss due to the residual uncertainty in the environment. The second term reflects a loss due to the average bias that the agent introduces with his choice. Finally, agent’s beliefs affect the objective only through the last term, which represents a loss due to variance in the agent’s actions beyond the adjustments that the principal herself would make.

This decomposition illustrates that the principal ideally wants $E_g[y(\tilde{\theta})|s] - E_f[\tilde{\theta}|s]$ to be constant. This is, the ideal agent is one who acts as if his bias was additive. Therefore, if
the expected conflict of interests is invariant in the signal, i.e. $E_f[y(\theta)|\tilde{s}] = E_f[\tilde{\theta}|\tilde{s}] + b$, the rational agent would be optimal since he is feasible and already behaves as the principal ideally wants. It turns out that this condition is also necessary for rationality to be optimal. Whenever the conditional expectation of the conflict of interest varies with the signal, there is a marginal deviation from rationality that strictly increases the principal’s expected payoff. This is achieved by decreasing the agent’s action after a signal realization leading to higher expected conflict of interests, while increasing the agent’s action after a realization inducing lower expected conflict of interests. The construction of a distribution that improves upon rationality follows the same logic as in the $n = m = 2$ case, the details are discussed in the proof of the following proposition (see appendix A).

**Proposition 2** The optimal agent is rational if and only if $E_f[c(\tilde{\theta})|\tilde{s}]$ is constant.

Moreover, because the marginals of $g$ equal those of $f$, $E_g[y(\tilde{\theta})|\tilde{s}] - E_f[\tilde{\theta}|\tilde{s}]$ can only equal one constant, which is $E_f[c(\tilde{\theta})]$. Therefore, for this ideal agent we have that $E_g[y(\tilde{\theta})|\tilde{s}] - E_f[y(\tilde{\theta})|\tilde{s}] = E_f[c(\tilde{\theta})] - E_f[c(\tilde{\theta})|\tilde{s}]$. Assuming that $E_f[c(\tilde{\theta})|\tilde{s} = s]$ is decreasing in $s$, the ideal agent’s optimal action would be below the rational agent’s action for low signals realizations, while the opposite is true for high ones. When $E_f[y(\tilde{\theta})|\tilde{s} = s]$ is increasing, this pattern corresponds to more extreme agent’s actions, a direct manifestation of overconfidence. As a result, the idea that overconfidence is optimal when $y(\tilde{\theta})$ and $c(\tilde{\theta})$ move in opposite directions generalizes beyond the $n = m = 2$ special case. The following result formalizes this intuition.

**Proposition 3** Assume that $|E_f[c(\tilde{\theta})|\tilde{s} = s] - E_f[c(\tilde{\theta})]|$ is not too big for all $s \in S$.

If $E_f[c(\tilde{\theta})|\tilde{s} = s]$ is decreasing in $s$, then any optimal agent acts as an overconfident agent. On the other hand, if $E_f[c(\tilde{\theta})|\tilde{s} = s]$ is increasing, any optimal agent acts as an underconfident agent.

First, note that uniqueness from the $n = m = 2$ case is necessarily lost. There exist several (typically a continuum of) distributions with the same marginals and conditional expectations. However, all optimal agents take the same actions. The previous result provides sufficient conditions for at least one optimal agent to be strictly ranked above or below the true distribution according to the concordance order. Moreover, all optimal agents must be unraked among themselves. This is, if two different distributions $g$ and $g'$ both solve the belief design problem, it cannot be that $g \geq g'$.
The proof of this proposition parallels that of proposition 1. We start by changing the principal’s choice from \( g \in \mathcal{G} \) to a matrix of elementary transformations \( t \in \mathbb{R}^{(n-1) \times (m-1)} \). Let \( t_{kl} \) denote a typical entry of the matrix \( t \). Note that \( t_{kl} > 0 \) moves probability mass from \( \theta_{k+1} \) to \( \theta_k \) after \( s_l \) is realized, while the opposite happens after \( s_{l+1} \). Informally, a positive elementary transformation moves mass from discordant pairs of states and signal realizations to the adjacent concordant pairs. The next step is to analyze the first order conditions that optimal elementary transformations need to satisfy. Then, I propose a family of transformations that satisfy these conditions. When all entries of \( t \) are positive, we get a distribution that dominates the initial one in the concordance order. The assumptions in proposition 3 guarantee that the proposed solution is both feasible and positive (or negative), which proves the existence of an overconfident (or underconfident) optimal agent.

In what follows I explore the implications of additional tools available to the principal. I go back to the assumption that \( n = m = 2 \). First, I will study how belief design is affected by availability of action-contingent transfers. I will argue that transfers do not affect optimal beliefs as long as the expected conflict of interests is not too far away from zero. Moreover, in the optimum each tool (belief and contract design) is used for different purposes. Additionally, I consider the possibility that the principal can make the choice herself. This imposes some restrictions on the characteristics of an agent who is actually allowed to make the choice: for the principal to delegate the choice, agent’s confidence must be sufficiently high.

4 Transfers

Conflicting preferences among its members is a prominent challenge that organizations face. Provision of monetary incentives is a particularly relevant tool that can be used to mitigate the pernicious effects of agency frictions. In this section, I consider the interaction between belief design and action-contingent transfers. In particular, in addition to belief design, the principal is also allowed to commit to non-negative payments contingent on the agent’s action. We focus again on the \( n = m = 2 \) case. The timing is as follows:

1. Belief and contract design: the principal chooses \( g \in \mathcal{G} \) and \( w : \mathbb{R} \rightarrow \mathbb{R}_+ \).
2. Nature draws \((\theta, s)\) according to \( f \).
3. The agent observes \( s \) and chooses \( x \in \mathbb{R} \).
Payoffs are given by $-(x-\theta)^2 - w(x)$ for the principal and by $-(x-y(\theta))^2 + w(x)$ for the agent.

As a first step, we can think of the problem as the principal recommending action $x_i$ after signal realization $s_i$, paying $w_i$ after that action is observed, and paying zero when a non-recommended action is observed. Additionally, in the $n = m = 2$ case, belief design can be thought as choosing a confidence level $\varepsilon \in [\underline{\varepsilon}, \bar{\varepsilon}]$. Therefore, it suffices for the principal to choose a tuple $(x_1, x_2, w_1, w_2, \varepsilon)$ consisting of recommended actions, payments for those actions, and a confidence level.

The recommended actions must be incentive compatible given promised transfers and agent’s confidence. After each signal realization two deviations are relevant: to the other recommended action and to the best action among those that were not recommended. The best deviation to an action yielding no transfer corresponds to choosing $E_{\varepsilon}\left[y(\tilde{\theta}) | \tilde{s} = s_i\right]$ after signal $s_i$, which yields an expected payoff of $-Var_{\varepsilon}\left(y(\tilde{\theta}) | \tilde{s} = s_i\right)$.

The main result in this section provides conditions under which the optimal beliefs coincide with those described in subsection 3.1 in which transfers were not available. In the optimum, each tool plays a different role: transfers are used to decrease the average bias in the agent’s action, while beliefs are used to distribute such bias across signal realizations.

**Proposition 4** Assume that $|E_f[c(\tilde{\theta})]| \leq E_f[\tilde{\theta} | \tilde{s} = s_2] - E_f[\tilde{\theta} | \tilde{s} = s_1]$. The availability of transfers does not change the optimal beliefs (thus, proposition 1 applies) and $w_1^* = w_2^* = E_f[c(\tilde{\theta})]^2$.

This result also highlights the effects of belief design on optimal transfers. When belief are optimally chosen, wages do not change with the actions the agent takes in equilibrium. On the other hand, when only the rational agent is available, the optimum for the principal is given by

$$x_j = \frac{E_f[\tilde{\theta} | \tilde{s} = s_j] + E_f[y(\tilde{\theta}) | \tilde{s} = s_j]}{2}$$

$$w_j = \frac{1}{4}E_f[c(\tilde{\theta}) | \tilde{s} = s_j]^2.$$

Therefore, unless $E_f[c(\tilde{\theta}) | \tilde{s} = s_j]$ is constant (in which case the rational agent is indeed optimal), wages are different for both recommended actions. This is, optimal belief-based selection leads to “flatter” compensation schemes.

It is worth noting that Ashworth and Sasso (2019) study the interaction between optimal delegation sets and transfers in a similar setting. When the principal and the agent only differ in their level of confidence, the optimal mechanism does not use transfers.
5 Delegation

Consider the case in which the principal can also decide whether to delegate the choice or to centralize it. In this section, I discuss when it is the case that the principal actually prefers delegation and its implications about the optimal agent’s confidence.

The main takeaway is that centralization is a substitute for extreme underconfidence. The intuition is simple: if the optimal agent is not sufficiently using the information, it would be better for the principal to make the choice herself in order to avoid the conflict of interests. The principal would only rely on the agent to use his private information; otherwise, she would be better off avoiding the bias that the agent introduces to the decision.

The following result shows that the optimal agent must be sufficiently confident for the choice to be delegated to him.

**Proposition 5** The choice is delegated to the optimal agent if and only if

\[
\varepsilon^* \geq \frac{f_S(s_1)f_S(s_2)E_f[c(\tilde{\theta})]^2}{|f|(y(\theta_2) - y(\theta_1))(\theta_2 - \theta_1)} - |f|.
\]

Naturally, an agent that is on average unbiased (i.e. \(E_f[c(\tilde{\theta})] = 0\)) would act just as the principal in the absence of any information. Therefore, when \(E_f[c(\tilde{\theta})] = 0\) the choice would be delegated even to a maximally underconfident agent (one who thinks that signals are uninformative). On the other hand, whenever \(E_f[c(\tilde{\theta})] \neq 0\) the agent’s confidence must be strictly above \(-|f|\) (the confidence of a maximally underconfident agent) for delegation to be optimal.

While extreme underconfidence never leads to delegation to an agent that is on average biased, it can be optimal to delegate to an extremely overconfident agent.\(^{12}\) Therefore, while the two phenomena are modeled symmetrically, the possibility to centralize decision making highlights a key difference between over- and underconfidence.

---

\(^{12}\)Consider the following example: \(\theta_1 = 0, \theta_2 = 10, y(\theta) = 3 + \theta/3, f(\theta_i, s_i) = 0.4, \) and \(f(\theta_i, s_{-i}) = 0.1.\) We have that \(\varepsilon^* = 0.3 > \varepsilon = 0.1,\) which implies that the optimal agent is maximally overconfident, interpreting signals at face value (after seeing \(s_i\) this agent would be convinced that the state is \(\theta_i\)). The expected payoff from delegation is -17.89, while the expected payoff from centralization is -25. Therefore, it is optimal to delegate to the maximally overconfident agent.
6 Conclusions

There is abundant evidence about the pervasiveness of overconfident employees. This paper discusses situations in which a firm is willing to select an employee not despite of his overconfidence but precisely because of it. Thus, a reason for overconfidence to be ubiquitous is that the conditions that lead to its optimality are relevant in many environments. Under-responsiveness to the firm’s interests is “bread-and-butter” when employees prioritize a quiet life over adjusting their behavior to current conditions and it can be (at least partially) alleviated by the employee’s misperception of being more informed.

Moreover, belief-based selection interacts meaningfully with some other measures that the firm could take to mitigate agency frictions. For example, an employee with optimal beliefs would face “flatter” compensations schemes than his rational counterpart. Additionally, centralizing decision-making is a natural substitute for extreme underconfidence, while it can be optimal to delegate to a “fully” overconfident employee.

The main methodological innovation, the belief design problem, allows the firm to exploit the heterogeneity in applicants’ confidence by selecting the candidate with most favorable beliefs (keeping fixed all other individual characteristics). In this context, I show that belief-based selection leads to employees with a common feature: they tend to act as if their disagreement with the firm was invariant to their private information. As a result, the firm prefers a rational agent if and only if this disagreement does not change with the employee’s observations to begin with. On the other hand, overconfidence helps when this conflict of interests moves in the opposite direction than the employee’s preferred action. As a tool, belief-design is flexible can be adjusted to systematically think about other belief-based biases, such as overoptimism.

Two assumptions were maintained through this exercise: that the potential employees are sufficiently diverse in their beliefs and that their characteristics are perfectly observed by the firm. The first assumption is made to provide a benchmark. The second is motivated by evidence suggesting that firms can learn quite rapidly about its employees’ characteristics (Lange, 2007; Hansen et al., 2021). Issues of a constrained set of available employees as well as asymmetric information about the applicants’ characteristics are left for future research.

These findings illustrate interesting ways in which personality traits, such as confidence, can impact labor market outcomes, such as wages and career choices (see Schulz and Thöni, 2016). Similarly, they help explain several documented managerial and organizational practices.
targeted towards altering employees’ perceptions (see Haran et al., 2010; Meikle et al., 2016). Additionally, if confidence has the potential to affect expected outcomes (in the labor market or otherwise), we may expect individuals to invest in “adjusting” this personal characteristic according to their goals.\footnote{13
See Kreps (2019) for a discussion about the role of business schools in boosting students’ confidence.}

Finally, while this paper specifically focuses on the role for overconfidence inside organizations, the main mechanism is likely to operate in several other types of social interactions where conflicting preferences and private information play a significant role (such as friendships and romantic relationships).
References

Appendix

Appendix A: Omitted proofs

Proof of Proposition 1

The belief design problem is as follows

$$\max_{\varepsilon \in [\varepsilon, \bar{\varepsilon}]} U(f + \varepsilon A)$$

we have

$$U(f + \varepsilon A) = -f(\theta_1, s_1) \left( \mathbb{E}_\varepsilon [y(\tilde{\theta})|\tilde{s} = s_1] - \theta_1 \right)^2 - f(\theta_1, s_2) \left( \mathbb{E}_\varepsilon [y(\tilde{\theta})|\tilde{s} = s_2] - \theta_1 \right)^2$$

$$- f(\theta_2, s_1) \left( \mathbb{E}_\varepsilon [y(\tilde{\theta})|\tilde{s} = s_1] - \theta_2 \right)^2 - f(\theta_2, s_2) \left( \mathbb{E}_\varepsilon [y(\tilde{\theta})|\tilde{s} = s_2] - \theta_2 \right)^2$$

where

$$\mathbb{E}_\varepsilon [y(\tilde{\theta})|\tilde{s} = s_1] = \mathbb{E}_f [y(\tilde{\theta})|\tilde{s} = s_1] - \frac{\varepsilon}{f_S(s_1)} \left[ y(\theta_2) - y(\theta_1) \right]$$

$$\mathbb{E}_\varepsilon [y(\tilde{\theta})|\tilde{s} = s_2] = \mathbb{E}_f [y(\tilde{\theta})|\tilde{s} = s_2] + \frac{\varepsilon}{f_S(s_2)} \left[ y(\theta_2) - y(\theta_1) \right]$$

Thus,

$$\frac{\partial U(f + \varepsilon A)}{\partial \varepsilon} = 2 \left[ y(\theta_2) - y(\theta_1) \right] \left[ \mathbb{E}_\varepsilon [y(\tilde{\theta})|\tilde{s} = s_1] - \mathbb{E}_f [\tilde{\theta}|\tilde{s} = s_1] - \mathbb{E}_\varepsilon [y(\tilde{\theta})|\tilde{s} = s_2] + \mathbb{E}_f [\tilde{\theta}|\tilde{s} = s_2] \right]$$

We can see that $U$ is strictly concave in $\varepsilon$:

$$\frac{\partial^2 U(f + \varepsilon A)}{\partial \varepsilon^2} = -2 \frac{[y(\theta_2) - y(\theta_1)]^2}{f_S(s_1)f_S(s_2)} < 0$$

The first-order condition is given by

$$\mathbb{E}_\varepsilon [y(\tilde{\theta})|\tilde{s} = s_1] - \mathbb{E}_f [\tilde{\theta}|\tilde{s} = s_1] = \mathbb{E}_\varepsilon [y(\tilde{\theta})|\tilde{s} = s_2] - \mathbb{E}_f [\tilde{\theta}|\tilde{s} = s_2]$$

which is equivalent to

$$\mathbb{E}_f [c(\tilde{\theta})|\tilde{s} = s_1] - \frac{\varepsilon}{f_S(s_1)} \left[ y(\theta_2) - y(\theta_1) \right] = \mathbb{E}_f [c(\tilde{\theta})|\tilde{s} = s_2] + \frac{\varepsilon}{f_S(s_2)} \left[ y(\theta_2) - y(\theta_1) \right]$$

Note that

$$\mathbb{E}_f [c(\tilde{\theta})|\tilde{s} = s_2] - \mathbb{E}_f [c(\tilde{\theta})|\tilde{s} = s_1] = [c(\theta_2) - c(\theta_1)] \frac{f(\theta_2, s_2)f(\theta_1, s_1) - f(\theta_1, s_2)f(\theta_2, s_1)}{f_S(s_1)f_S(s_2)}$$
Therefore, the interior solution (if exists) is given by
\[
\varepsilon^* = -\frac{c(\theta_2) - c(\theta_1)}{y(\theta_2) - y(\theta_1)} \left[ f(\theta_2, s_2) f(\theta_1, s_1) - f(\theta_1, s_2) f(\theta_2, s_1) \right]
\]
\[
= -\frac{Cov(c(\bar\theta), y(\bar\theta))}{Var(y(\bar\theta))} \left[ f(\theta_2, s_2) f(\theta_1, s_1) - f(\theta_1, s_2) f(\theta_2, s_1) \right]
\]
Since by assumption \(f(\theta_2, s_2) f(\theta_1, s_1) > f(\theta_1, s_2) f(\theta_2, s_1)\), we have that the sign of \(\varepsilon^*\) equals the sign of \(-Cov(c(\bar\theta), y(\bar\theta))\). Finally, if \(\varepsilon^* \notin [\underline{\varepsilon}, \overline{\varepsilon}]\) then the solution is in a corner and will still have the same sign as \(\varepsilon^*\).

**Proof of Proposition 2**

Optimality of rationality when \(E_f[c(\bar\theta) | \bar{s}]\) is constant follows directly from the decomposition in subsection 3.2.

On the other hand, assume that \(E_f[c(\bar\theta) | \bar{s}]\) is not constant. This is, there exist signal realizations \(s_l\) and \(s_{\ell'}\) with \(E_f[c(\bar\theta) | \bar{s} = s_{\ell'}] > E_f[c(\bar\theta) | \bar{s} = s_l]\). Choose any two states \(\theta_k\) and \(\theta_{\ell'},\) where \(\theta_k < \theta_{\ell'}\), and define \(g_\varepsilon \in \Delta(\Theta \times S)\) as follows
\[
g_\varepsilon(\theta, s) := \begin{cases} 
  f(\theta, s) + \varepsilon & \text{if } (\theta, s) \in \{(\theta_{\ell'}, s_{\ell'}), (\theta_k, s_l)\} \\
  f(\theta, s) - \varepsilon & \text{if } (\theta, s) \in \{(\theta_k, s_{\ell'}), (\theta_{\ell'}, s_l)\} \\
  f(\theta, s) + \varepsilon & \text{otherwise}
\end{cases}
\]
Note that \(g_\varepsilon\) remains feasible whenever \(\varepsilon \in [\underline{\varepsilon}, \overline{\varepsilon}]\), where
\[
\underline{\varepsilon} := \min \{f(\theta_{\ell'}, s_{\ell'}), 1 - f(\theta_k, s_{\ell'}), 1 - f(\theta_{\ell'}, s_l), f(\theta_k, s_l)\}
\]
\[
\overline{\varepsilon} := \min \{1 - f(\theta_{\ell'}, s_{\ell'}), f(\theta_k, s_{\ell'}), f(\theta_{\ell'}, s_l), 1 - f(\theta_k, s_l)\}
\]
The full support assumption imply that \(\underline{\varepsilon} < 0 < \overline{\varepsilon}\).

Note that when agent’s beliefs are given by \(g_\varepsilon\), he takes the following action after a given signal realization \(s\)
\[
E_{g_\varepsilon} \left[ y(\bar{\theta}) | \bar{s} = s \right] = \begin{cases} 
  E_f \left[ y(\bar{\theta}) | \bar{s} = s \right] - \varepsilon \frac{y(\theta_{\ell'}) - y(\theta_k)}{f_{\bar{s}}(s_l)} & \text{if } s = s_l \\
  E_f \left[ y(\bar{\theta}) | \bar{s} = s \right] + \varepsilon \frac{y(\theta_{\ell'}) - y(\theta_k)}{f_{\bar{s}}(s_{\ell'})} & \text{if } s = s_{\ell'} \\
  E_f \left[ y(\bar{\theta}) | \bar{s} = s \right] & \text{otherwise}
\end{cases}
\]
Therefore, the principal’s expected payoff from choosing \( g_\varepsilon \) is given by

\[
U(g_\varepsilon) = U(f) - \varepsilon^2 \left[ y(\theta_{k'}) - y(\theta_k) \right]^2 \left( \frac{1}{f_S(s_{l'})} + \frac{1}{f_S(s_l)} \right)
- 2\varepsilon \left[ y(\theta_{k'}) - y(\theta_k) \right] \left( \mathbb{E}_f[c(\tilde{\theta}) | \tilde{s} = s_{l'}] - \mathbb{E}_f[c(\tilde{\theta}) | \tilde{s} = s_l] \right)
\]

Differentiating this expression with respect to \( \varepsilon \) we get

\[
\frac{\partial U(g_\varepsilon)}{\partial \varepsilon} = -2 \left[ y(\theta_{k'}) - y(\theta_k) \right] \varepsilon \left( \frac{1}{f_S(s_{l'})} + \frac{1}{f_S(s_l)} \right)
- 2 \left[ y(\theta_{k'}) - y(\theta_k) \right] \left( \mathbb{E}_f[c(\tilde{\theta}) | \tilde{s} = s_{l'}] - \mathbb{E}_f[c(\tilde{\theta}) | \tilde{s} = s_l] \right)
\]

Finally, \( y(\theta_{k'}) \neq y(\theta_k) \) and \( \mathbb{E}_f[c(\tilde{\theta}) | \tilde{s} = s_{l'}] > \mathbb{E}_f[c(\tilde{\theta}) | \tilde{s} = s_l] \) imply that this derivative never equals 0 at \( \varepsilon = 0 \)

\[
\frac{\partial U(g_\varepsilon)}{\partial \varepsilon} \bigg|_{\varepsilon=0} = -2 \left[ y(\theta_{k'}) - y(\theta_k) \right] \left( \mathbb{E}_f[c(\tilde{\theta}) | \tilde{s} = s_{l'}] - \mathbb{E}_f[c(\tilde{\theta}) | \tilde{s} = s_l] \right) \neq 0
\]

Therefore, \( f \) cannot solve the belief design problem. ■

**Proof of Proposition 3**

We start with the observation that any \( g \in \mathcal{G} \) can be decomposed as follows

\[
g = f + \begin{bmatrix}
t_{t_{11}} & -t_{t_{11}} + t_{t_{12}} & \cdots & \cdots & \cdots & \cdots & t_{t_{1,m-2}} + t_{t_{1,m-1}} & \cdots & -t_{t_{1,m-2}} + t_{t_{1,m-1}} \\
-t_{t_{11}} + t_{t_{21}} & t_{t_{11}} - t_{t_{12}} - t_{t_{21}} + t_{t_{22}} & \cdots & \cdots & \cdots & \cdots & -t_{t_{1,m-2}} + t_{t_{1,m-1}} & \cdots & -t_{t_{1,m-2}} + t_{t_{1,m-1}} \\
t_{t_{21}} - t_{t_{22}} + t_{t_{31}} & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\
\vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\
n_{t_{n-2,1}} + n_{t_{n-1,1}} - n_{t_{n-1,1}} & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\
n_{t_{n-1,1}} - t_{t_{n-1,1}} & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\
\end{bmatrix}
\]

\[
f = f + \begin{bmatrix}
1 & 0 & \cdots & 0 & 0 \\
-1 & 1 & \cdots & 0 & 0 \\
0 & -1 & \ddots & \ddots & \ddots \\
\vdots & \vdots & \ddots & \ddots & \ddots \\
0 & 0 & \cdots & -1 & 1 \\
0 & 0 & \cdots & 0 & -1 \\
\end{bmatrix}
\]

\[
C \in \mathbb{R}^{n \times (n-1)}
\]

\[
t_{t_{E(n-1) \times (m-1)}} = \begin{bmatrix}
t_{t_{11}} & t_{t_{12}} & \cdots & t_{1,m-1} \\
t_{t_{21}} & t_{t_{22}} & \cdots & t_{2,m-1} \\
\vdots & \vdots & \ddots & \ddots \\
t_{t_{n-1,1}} & t_{t_{n-1,2}} & \cdots & t_{n-1,m-1} \\
\end{bmatrix}
\]

\[
B \in \mathbb{R}^{(m-1) \times m}
\]

Note that each \( t_{kl} \) affects posterior beliefs only after signal realizations \( s_l \) and \( s_{l+1} \). Moreover, a transformation \( t_{kl} > 0 \) moves probability mass from \( \theta_{k+1} \) to \( \theta_k \) after \( s_l \), while the opposite happens after \( s_{l+1} \).
Let $\delta(t, s_j)$ denote the difference between the actions of an agent that interprets signals according to $t$ and those of the rational agent. This is,

$$\delta(t, s_j) := \mathbb{E}_g [y(\tilde{\theta})|\tilde{s} = s_j] - \mathbb{E}_f [y(\tilde{\theta})|\tilde{s} = s_j] = \frac{1}{f_S(s_j)} \sum_{i=1}^{n-1} [y(\theta_{i+1}) - y(\theta_i)] [t_{i,j-1} - t_{ij}]$$

In particular, since $t_{i0} = t_{im} = 0$ we have that

$$\delta(t, s_1) = -\frac{1}{f_S(s_1)} \sum_{i=1}^{n-1} [y(\theta_{i+1}) - y(\theta_i)] t_{i1} \quad \text{and} \quad \delta(t, s_m) = \frac{1}{f_S(s_m)} \sum_{i=1}^{n-1} [y(\theta_{i+1}) - y(\theta_i)] t_{i,m-1}$$

As a result

$$\frac{\partial \delta(t, s_j)}{\partial t_{kl}} = \begin{cases} \frac{-y(\theta_{k+1}) - y(\theta_k)}{f_S(s_l)} & \text{if } j = l \\ \frac{y(\theta_{k+1}) - y(\theta_k)}{f_S(s_{l+1})} & \text{if } j = l + 1 \\ 0 & \text{otherwise} \end{cases}$$

On the other hand, $g \in \mathcal{G}$ if and only if $t_{i-1,j-1} - t_{i-1,j} - t_{i,j-1} + t_{ij} \in [-f(\theta_i, s_j), 1 - f(\theta_i, s_j)]$ for all $i \in \{1, \ldots, n\}$ and $j \in \{1, \ldots, m\}$, where $t_{0j} = t_{i0} = t_{nj} = t_{im} = 0$. Let $\mathcal{T}$ denote the set of feasible transformations. Note that the full-support assumption guarantees that the interior of $\mathcal{T}$, denoted $\mathcal{T}^\circ$, is non-empty (in particular the $0 \times m$-matrix belongs to $\mathcal{T}^\circ$).

Therefore, the belief design problem corresponds to choosing $t \in \mathcal{T}$ to maximize $U(f + AtB)$. Since $U(f + AtB)$ is continuous in $t$ and $\mathcal{T}$ is a compact set, it follows that this problem has a solution.

Note that $g \succeq f$ if and only if $t_0 \geq 0$ for all $i \in \{1, \ldots, n-1\}$ and $j \in \{1, \ldots, m-1\}$. Therefore, if $t^* \succeq 0$ solves this problem, we would say that the optimal agent is overconfident.

We can decompose the objective function as follows

$$U(g) = -\mathbb{E}_f [\delta(t, \tilde{s})^2] - 2\mathbb{E}_f [\delta(t, \tilde{s}) \mathbb{E}_f [c(\tilde{\theta})|\tilde{s}]] + U(f)$$

Thus,

$$\frac{\partial U(f + CtB)}{\partial t_{kl}} = 2[y(\theta_{k+1}) - y(\theta_k)] [\delta(t, s_l) + \mathbb{E}_f [c(\tilde{\theta})|\tilde{s} = s_l] - \delta(t, s_{l+1}) - \mathbb{E}_f [c(\tilde{\theta})|\tilde{s} = s_{l+1}]]$$

Since we assumed that $y(\theta_{k+1}) > y(\theta_k)$, we have that in any optimum $t^* \in \mathcal{T}^\circ$ the following expression must hold for each $l \in \{1, \ldots, m-1\}$

$$\delta(t^*, s_l) + \mathbb{E}_f [c(\tilde{\theta})|\tilde{s} = s_l] = \Delta(t^*, s_{l+1}) + \mathbb{E}_f [c(\tilde{\theta})|\tilde{s} = s_{l+1}]$$

\[\text{[1] For a more general version and proof of this statement see Tchen (1980) or Epstein and Tanny (1980).}\]
Expression (1) requires \( \delta(t^*, s_l) + \mathbb{E}_f [c(\tilde{\theta})|\tilde{s} = s_l] \) to be constant in \( l \). Moreover, \( \mathbb{E}_f [\delta(t^*, s_l)] = 0 \) implies that this constant must equal \( \mathbb{E}_f [c(\tilde{\theta})] \). Therefore, in any optimum \( t^* \in \mathcal{T} \) we must have \( \delta(t^*, s_l) = \mathbb{E}_f [c(\tilde{\theta})] - \mathbb{E}_f [c(\tilde{\theta})|\tilde{s} = s_l] \) for all \( l \in \{1, \ldots, m\} \). Using the definition of \( \delta(t^*, s_l) \), we conclude that \( \mathbb{E}_f [\tilde{\theta}|\tilde{s} = s_l] = \mathbb{E}_f [c(\tilde{\theta})] + \mathbb{E}_f [\tilde{\theta}|\tilde{s} = s_l] \), i.e. the optimal agent behave as if the conflict of interest was constant.

Using the expression for \( \delta(t, s_l) \) in \( \delta(t^*, s_l) = \mathbb{E}_f [c(\tilde{\theta})] - \mathbb{E}_f [c(\tilde{\theta})|\tilde{s} = s_l] \) we get

\[
\frac{1}{f_{\mathcal{S}}(s_l)} \sum_{i=1}^{n-1} [y(\theta_{i+1}) - y(\theta_i)] [t_{i,t-1}^* - t_{i,t}^*] = \mathbb{E}_f [c(\tilde{\theta})] - \mathbb{E}_f [c(\tilde{\theta})|\tilde{s} = s_l]
\]

(2)

Iterating (2) we get the following expression for all \( l \in \{1, \ldots, m-1\} \)

\[
\sum_{i=1}^{n-1} [y(\theta_{i+1}) - y(\theta_i)] t_{i,l}^* = \frac{\sum_{j=1}^{l} f_{\mathcal{S}}(s_j) (\mathbb{E}_f [c(\tilde{\theta})|\tilde{s} = s_j] - \mathbb{E}_f [c(\tilde{\theta})])}{y(\theta_{k+1}) - y(\theta_k)}
\]

(3)

Now, consider the matrix of transformations \( t^\phi \in \mathbb{R}^{(n-1) \times (m-1)} \) with typical entry defined as follows

\[
t^\phi_{kl} = \frac{\sum_{j=1}^{l} f_{\mathcal{S}}(s_j) (\mathbb{E}_f [c(\tilde{\theta})|\tilde{s} = s_j] - \mathbb{E}_f [c(\tilde{\theta})])}{y(\theta_{k+1}) - y(\theta_k)}
\]

where \( \phi = (\phi_1, \ldots, \phi_{n-1}) \in \Delta^{n-1}. \)

By construction \( t^\phi \) satisfies (3). Under the assumptions that \( \mathbb{E}_f [c(\tilde{\theta})|\tilde{s} = s] \) is strictly decreasing in \( s \) and that \( y(\cdot) \) is strictly increasing we have that \( t^\phi_{kl} \geq 0 \). Thus, if \( t^\phi \in \mathcal{T} \) for some \( \phi \in \Delta^{n-1} \) then it solves the belief design problem and we can conclude that there is an overconfident optimal agent.

Let \( \alpha := \max_{s \in \mathcal{S}} \left| \mathbb{E}_f [c(\tilde{\theta})|\tilde{s} = s] - \mathbb{E}_f [c(\tilde{\theta})] \right| \). Therefore,

\[
t^\phi_{kl} = \left| t^\phi_{kl} \right| = \left| \sum_{j=1}^{l} f_{\mathcal{S}}(s_j) \frac{(\mathbb{E}_f [c(\tilde{\theta})|\tilde{s} = s_j] - \mathbb{E}_f [c(\tilde{\theta})])}{y(\theta_{k+1}) - y(\theta_k)} \phi_k \right| \leq \alpha \frac{\phi_k}{y(\theta_{k+1}) - y(\theta_k)}
\]

This implies that

\[
t^\phi_{i,1} - t^\phi_{i,1} - t^\phi_{i,1} - t^\phi_{i,1} - t^\phi_{i,1} \geq -\alpha \left[ \frac{\phi_i}{y(\theta_{i+1}) - y(\theta_i)} + \frac{\phi_{i-1}}{y(\theta_i) - y(\theta_{i-1})} \right]
\]

and

\[
t^\phi_{i,1} - t^\phi_{i,1} - t^\phi_{i,1} \leq t^\phi_{i,1} - t^\phi_{i,1} + t^\phi_{i,1} \leq \alpha \left[ \frac{\phi_i}{y(\theta_{i+1}) - y(\theta_i)} + \frac{\phi_{i-1}}{y(\theta_i) - y(\theta_{i-1})} \right]
\]

Therefore, there exist a \( \tilde{\alpha}(\phi) > 0 \) such that \( \alpha < \tilde{\alpha}(\phi) \) implies that \( t^\phi \) is feasible. Finally, let \( \tilde{\alpha} := \sup_{\phi \in \Delta^{n-1}} \tilde{\alpha}(\phi) > 0 \). Thus, whenever \( \alpha < \tilde{\alpha} \) there exists some \( \phi \in \Delta^{n-1} \) such that \( t^\phi \in \mathcal{T} \), which gives the desired result. \( \blacksquare \)

\(^{15} \Delta^n \) denotes the \( a \)-dimensional simplex, i.e. the set of \( a \)-vectors satisfying \( \phi_i \geq 0 \) and \( \sum_{i=1}^{n} \phi_i = 1 \).
Proof of Proposition 4

The four incentive compatibility constraints are given by

\[-\mathbb{E}_\epsilon \left[ (x_1 - y(\hat{\theta}))^2 | \hat{s} = s_1 \right] + w_1 \geq -\mathbb{E}_\epsilon \left[ (x_2 - y(\hat{\theta}))^2 | \hat{s} = s_1 \right] + w_2\]
\[-\mathbb{E}_\epsilon \left[ (x_1 - y(\hat{\theta}))^2 | \hat{s} = s_1 \right] + w_1 \geq \text{Var}_\epsilon (y(\hat{\theta}) | \hat{s} = s_1)\]
\[-\mathbb{E}_\epsilon \left[ (x_2 - y(\hat{\theta}))^2 | \hat{s} = s_2 \right] + w_2 \geq -\mathbb{E}_\epsilon \left[ (x_1 - y(\hat{\theta}))^2 | \hat{s} = s_2 \right] + w_1\]
\[-\mathbb{E}_\epsilon \left[ (x_2 - y(\hat{\theta}))^2 | \hat{s} = s_2 \right] + w_2 \geq \text{Var}_\epsilon (y(\hat{\theta}) | \hat{s} = s_2)\]

Thus, the principal’s problem is

\[\max \{x_1, x_2, w_1, w_2, \epsilon\} \quad -f_S(s_1) \left( \mathbb{E}_\epsilon \left[ (x_1 - \hat{\theta})^2 | \hat{s} = s_1 \right] + w_1 \right) - f_S(s_2) \left( \mathbb{E}_\epsilon \left[ (x_2 - \hat{\theta})^2 | \hat{s} = s_2 \right] + w_2 \right)\]

subject to the incentive compatibility constraints that can be expressed as

\[
\begin{align*}
\text{[1]} & \quad w_2 - w_1 \leq x_2^2 - x_1^2 - 2(x_2 - x_1) \mathbb{E}_\epsilon \left[ y(\hat{\theta}) | \hat{s} = s_1 \right] \\
\text{[2]} & \quad w_1 \geq (x_1 - \mathbb{E}_\epsilon \left[ y(\hat{\theta}) | \hat{s} = s_1 \right])^2 \\
\text{[3]} & \quad w_2 - w_1 \geq x_2^2 - x_1^2 - 2(x_2 - x_1) \mathbb{E}_\epsilon \left[ y(\hat{\theta}) | \hat{s} = s_2 \right] \\
\text{[4]} & \quad w_2 \geq (x_2 - \mathbb{E}_\epsilon \left[ y(\hat{\theta}) | \hat{s} = s_2 \right])^2
\end{align*}
\]

A necessary condition for [1] and [3] is

\[(x_2 - x_1) \left( \mathbb{E}_\epsilon \left[ y(\hat{\theta}) | \hat{s} = s_2 \right] - \mathbb{E}_\epsilon \left[ y(\hat{\theta}) | \hat{s} = s_1 \right] \right) \geq 0\]

In any optimum we must have \(x_2 \geq x_1\). Otherwise, the principal is strictly better off asking for the average action regardless of the signal; such a change can only decrease the transfers to the agent. Therefore, we also need that \(\mathbb{E}_\epsilon \left[ y(\hat{\theta}) | \hat{s} = s_2 \right] \geq \mathbb{E}_\epsilon \left[ y(\hat{\theta}) | \hat{s} = s_1 \right]\).

Let \(\mu_i := \mathbb{E}_\epsilon \left[ y(\hat{\theta}) | \hat{s} = s_i \right]\) and \(\mu := (\mu_1 + \mu_2)/2\). The three possible cases are:

28
The subsequent analysis will be divided in the previous cases. Since beliefs enter principal’s objective only through wages, as a first step we will focus on choosing the beliefs that minimize expected transfers, defined as \( W(x_1, x_2, \mu_1) := f_S(s_1)w_1 + f_S(s_2)w_2 \), to implement a given pair of actions \((x_1, x_2)\). After that, we will solve for the optimal recommended actions. Finally, we will be able to conclude that under the assumption that \( |E_f[c(\hat{\theta})]| \leq E_f[\hat{\theta} | s = s_2] - E_f[\hat{\theta} | s = s_1] \) the solutions corresponds to the one in case 2.

**Case 1:** \( x_2 \geq x_1 > \bar{\mu} \)

\[
W(x_1, x_2, \mu_1) = (x_1 - \mu_1)^2 + f_S(s_2)(x_2^2 - x_1^2) - 2f_S(s_2)\mu_2(x_2 - x_1)
\]

Thus,

\[
\frac{\partial W(x_1, x_2, \mu_1)}{\partial \mu_1} = -2(x_1 - \mu_1) + 2f_S(s_1)(x_2 - x_1)
\]

\[
\frac{\partial^2 W(x_1, x_2, \mu_1)}{\partial \mu_1^2} = 2
\]

As a result, \( \mu_1^* := [1 + f_S(s_1)]x_1 - f_S(s_1)x_2 \) minimizes the expected wage. Note that \( \mu_1^* \leq x_1 \) with equality only if \( x_1 = x_2 \).

Additionally, \( \bar{\mu} < x_1 \) requires

\[
E_f[y(\hat{\theta})] < x_1 + f_S(s_1)[f_S(s_2) - f_S(s_1)](x_2 - x_1)
\]

By the envelope theorem

\[
\frac{\partial W(x_1, x_2, \mu_1^*)}{\partial x_1} = 2(x_1 - \mu_1^*) + 2f_S(s_2)(\mu_2^* - x_1)
\]

\[
\frac{\partial W(x_1, x_2, \mu_1^*)}{\partial x_2} = 2f_S(s_2)(x_2 - \mu_2^*)
\]

Now, we focus on optimal actions. The principal’s problem becomes

\[
\max_{\{x_1, x_2\}} \left\{-f_S(s_1)E_f[(x_1 - \hat{\theta})^2 | \hat{s} = s_1] - f_S(s_2)E_f[(x_2 - \hat{\theta})^2 | \hat{s} = s_2] - W(x_1, x_2, \mu_1^*)\right\}
\]

</table>
First order conditions are given by

\[-2 f_S(s_1) \left( x_1 - \mathbb{E}_f [\bar{\theta} | \bar{s} = s_1] \right) = \frac{\partial W(x_1, x_2, \mu^*_1)}{\partial x_1} \]
\[-2 f_S(s_2) \left( x_2 - \mathbb{E}_f [\bar{\theta} | \bar{s} = s_2] \right) = \frac{\partial W(x_1, x_2, \mu^*_2)}{\partial x_2} \]

equivalently,

\[-f_S(s_1) \left( x_1 - \mathbb{E}_f [\bar{\theta} | \bar{s} = s_1] \right) = x_1 - \mu^*_1 + f_S(s_2)(\mu^*_2 - x_1) \]
\[-(x_2 - \mathbb{E}_f [\bar{\theta} | \bar{s} = s_2]) = x_2 - \mu^*_2 \]

Thus, the following system of linear equations characterizes the optimum:

\[ x^*_1 = \frac{\mu^*_1 + \mathbb{E}_f [\bar{\theta} | \bar{s} = s_1]}{2} - \frac{f_S(s_2)}{2f_S(s_1)} (\mu^*_2 - \mu^*_1) \]
\[ x^*_2 = \frac{\mu^*_2 + \mathbb{E}_f [\bar{\theta} | \bar{s} = s_2]}{2} \]
\[ \mu^*_1 = \left[ 1 + f_S(s_1) \right] x^*_1 - f_S(s_1) x^*_2 \]
\[ \mu^*_2 = \frac{\mathbb{E}_f [y(\bar{\theta})] - f_S(s_1) \mu^*_1}{f_S(s_2)} \]

The solution is given by

\[
\begin{bmatrix}
  x^*_1 \\
  x^*_2 \\
  \mu^*_1 \\
  \mu^*_2
\end{bmatrix} =
\begin{bmatrix}
\frac{1 + f_S(s_2)}{2[1 - f_S(s_1)f_S(s_2)]} & \frac{f_S(s_1)^2 - 2f_S(s_1)f_S(s_2)}{4[1 - f_S(s_1)f_S(s_2)]} & \frac{f_S(s_1)f_S(s_2)[1 + f_S(s_1)]}{4[1 - f_S(s_1)f_S(s_2)]} \\
\frac{f_S(s_2)}{2[1 - f_S(s_1)f_S(s_2)]} & \frac{f_S(s_1)^2[1 + f_S(s_1)]}{4[1 - f_S(s_1)f_S(s_2)]} & \frac{[1 + f_S(s_1)^2]f_S(s_2)}{4[1 - f_S(s_1)f_S(s_2)]} \\
\frac{1}{1 - f_S(s_1)f_S(s_2)} & -\frac{f_S(s_1)f_S(s_2)[1 + f_S(s_1)]}{1 - f_S(s_1)f_S(s_2)} & \frac{f_S(s_1)^2f_S(s_2)}{1 - f_S(s_1)f_S(s_2)} \\
\frac{f_S(s_2)}{1 - f_S(s_1)f_S(s_2)} & \frac{f_S(s_1)^2[1 + f_S(s_1)]}{1 - f_S(s_1)f_S(s_2)} & -\frac{f_S(s_1)^3}{1 - f_S(s_1)f_S(s_2)}
\end{bmatrix}
\begin{bmatrix}
\mathbb{E}_f [y(\bar{\theta})] \\
\mathbb{E}_f [\bar{\theta} | \bar{s} = s_1] \\
\mathbb{E}_f [\bar{\theta} | \bar{s} = s_2]
\end{bmatrix}
\]

Note that

\[(\mu^*_2 - \mu^*_1) \frac{1 - f_S(s_1)f_S(s_2)}{f_S(s_1)} = -\mathbb{E}_f \left[ c(\bar{\theta}) \right] - \left[ \mathbb{E}_f [\bar{\theta} | \bar{s} = s_2] - \mathbb{E}_f [\bar{\theta} | \bar{s} = s_1] \right] \]

therefore \(\mu^*_2 \geq \mu^*_1\) if and only if \(\mathbb{E}_f [\bar{\theta} | \bar{s} = s_1] \leq -\left[ \mathbb{E}_f [\bar{\theta} | \bar{s} = s_2] - \mathbb{E}_f [\bar{\theta} | \bar{s} = s_1] \right]\).

**Case 2:** \(x_1 \leq \bar{\mu} \leq x_2\)

We have

\[ W(x_1, x_2, \mu) = f_S(s_1) (x_1 - \mu_1)^2 + f_S(s_2) (x_2 - \mu_2)^2 \]
Thus, \[
\frac{\partial W(x_1, x_2, \mu_1)}{\partial \mu_1} = 2f_S(s_1)\left(x_2 - x_1 - (\mu_2 - \mu_1)\right)
\]
\[
\frac{\partial^2 W(x_1, x_2, \mu_1)}{\partial \mu_1^2} = \frac{2f_S(s_1)}{f_S(s_2)}
\]
As a result, \(\mu_2^* - \mu_1^* = x_2 - x_1\), equivalently \(\mu_1^* := \mathbb{E}_f[y(\hat{\theta})] - f_S(s_2)(x_2 - x_1)\), minimizes the expected wage.

Additionally, \(x_2 \geq \bar{\mu}^* \geq x_1\) requires
\[
\mathbb{E}_f[y(\hat{\theta})] \in \left[ x_1 + \frac{f_S(s_2) - f_S(s_1)}{2}(x_2 - x_1), x_2 + \frac{f_S(s_2) - f_S(s_1)}{2}(x_2 - x_1) \right]
\]

By the envelope theorem
\[
\frac{\partial W(x_1, x_2, \mu_1^*)}{\partial x_1} = 2f_S(s_1)(x_1 - \mu_1^*)
\]
\[
\frac{\partial W(x_1, x_2, \mu_1^*)}{\partial x_2} = 2f_S(s_2)(x_2 - \mu_2^*)
\]

Now, we focus on optimal actions. The first order conditions of the principal’s problem are given by
\[
-\left(x_1 - \mathbb{E}_f[\hat{\theta}|s = s_1]\right) = x_1 - \mu_1^*
\]
\[
-\left(x_2 - \mathbb{E}_f[\hat{\theta}|s = s_2]\right) = x_2 - \mu_2^*
\]

Thus, the following system of linear equations characterizes the optimum:
\[
x_1^* = \frac{\mu_1^* + \mathbb{E}_f[\hat{\theta}|s = s_1]}{2}
\]
\[
x_2^* = \frac{\mu_2^* + \mathbb{E}_f[\hat{\theta}|s = s_2]}{2}
\]
\[
\mu_1^* = \mathbb{E}_f[y(\hat{\theta})] - f_S(s_2)(x_2^* - x_1^*)
\]
\[
\mu_2^* = \frac{\mathbb{E}_f[y(\hat{\theta})] - f_S(s_1)\mu_1^*}{f_S(s_2)}
\]

The solution is given by
\[
x_1^* = \frac{\mathbb{E}_f[c(\hat{\theta})]}{2} + \mathbb{E}_f[\hat{\theta}|s = s_1]
\]
\[
\mu_1^* = \mathbb{E}_f[c(\hat{\theta})] + \mathbb{E}_f[\hat{\theta}|s = s_1]
\]
Note that \( x_1^* \leq \bar{\mu} \leq x_2^* \) is equivalent to \( |E_f[c(\tilde{\theta})]| \leq E_f[\tilde{\theta}|\tilde{s} = s_2] - E_f[\tilde{\theta}|\tilde{s} = s_1] \).

**Case 3:** \( x_2 < \bar{\mu} \)

We have

\[
W(x_1, x_2, \mu_1) = f_S(s_1)x_1^2 + f_S(s_2)x_2^2 + \mu_2 - 2x_2\mu_2 + 2f_S(s_1)\mu_1(x_2 - x_1)
\]

Thus,

\[
\frac{\partial W(x_1, x_2, \mu_1)}{\partial \mu_1} = -2\mu_2 \frac{f_S(s_1)}{f_S(s_2)} + 2x_2 \frac{f_S(s_1)}{f_S(s_2)} + 2f_S(s_1)(x_2 - x_1)
\]

\[
\frac{\partial^2 W(x_1, x_2, \mu_1)}{\partial \mu_1^2} = 2 \frac{f_S(s_1)^2}{f_S(s_2)^2}
\]

As a result, \( \mu_2^* := \min \left[ 1 + f_S(s_2) \right] x_2 - f_S(s_2)x_1 \) minimizes the expected wage. Note that \( \mu_2^* \geq x_2 \) with equality only if \( x_1 = x_2 \).

Additionally, \( \bar{\mu} > x_2 \) requires

\[
E_f[y(\tilde{\theta})] > x_2 + f_S(s_2) [f_S(s_2) - f_S(s_1)] (x_2 - x_1)
\]

By the envelope theorem

\[
\frac{\partial W(x_1, x_2, \mu_1^*)}{\partial x_1} = 2f_S(s_1)(x_1 - \mu_1^*)
\]

\[
\frac{\partial W(x_1, x_2, \mu_1^*)}{\partial x_2} = 2(x_2 - \mu_2^*) - 2f_S(s_1)(x_2 - \mu_1^*)
\]

Now, we focus on optimal actions. The first order conditions of the principal’s problem are given by

\[
-x_1 - E_f[\tilde{\theta}|\tilde{s} = s_1] = x_1 - \mu_1^*
\]

\[
-f_S(s_2) \left( x_2 - E_f[\tilde{\theta}|\tilde{s} = s_2] \right) = x_2 - \mu_2^* - f_S(s_1)(x_2 - \mu_1^*)
\]

Thus, the following system of linear equations characterizes the optimum:

\[
x_1^* = \frac{\mu_1^* + E_f[\tilde{\theta}|\tilde{s} = s_1]}{2}
\]

\[
x_2^* = \frac{\mu_2^* + E_f[\tilde{\theta}|\tilde{s} = s_2]}{2} + \frac{f_S(s_1)}{2f_S(s_2)} (\mu_2^* - \mu_1^*)
\]

\[
\mu_1^* = \frac{E_f[y(\tilde{\theta})] - f_S(s_2)\mu_2^*}{f_S(s_1)}
\]

\[
\mu_2^* = \left[ 1 + f_S(s_2) \right] x_2^* - f_S(s_2)x_1^*
\]

32
The solution is given by

$$\begin{bmatrix}
x_1^* \\
x_2^* \\
\mu_1^* \\
\mu_2^*
\end{bmatrix} = \begin{bmatrix}
\frac{f_S(s_1)}{2[1-f_S(s_1)f_S(s_2)]} & \frac{f_S(s_1)[1+f_S(s_2)]}{2[1-f_S(s_1)f_S(s_2)]} & \frac{f_S(s_2)}{2[1-f_S(s_1)f_S(s_2)]} & \frac{f_S(s_2)[1+f_S(s_2)]}{2[1-f_S(s_1)f_S(s_2)]} \\
\frac{1+f_S(s_1)}{2[1-f_S(s_1)f_S(s_2)]} & \frac{f_S(s_1)f_S(s_1)[1+f_S(s_2)]}{2[1-f_S(s_1)f_S(s_2)]} & \frac{f_S(s_2)^3-2f_S(s_1)f_S(s_2)}{2[1-f_S(s_1)f_S(s_2)]} & \frac{f_S(s_2)^2[1+f_S(s_2)]}{2[1-f_S(s_1)f_S(s_2)]} \\
\frac{f_S(s_1)}{1-f_S(s_1)f_S(s_2)} & -\frac{f_S(s_2)^3}{1-f_S(s_1)f_S(s_2)} & \frac{f_S(s_2)^2[1+f_S(s_2)]}{1-f_S(s_1)f_S(s_2)} & \frac{f_S(s_2)^3-2f_S(s_1)f_S(s_2)}{1-f_S(s_1)f_S(s_2)} \\
\frac{1}{1-f_S(s_1)f_S(s_2)} & \frac{f_S(s_1)f_S(s_1)^2}{1-f_S(s_1)f_S(s_2)} & -\frac{f_S(s_1)f_1(s_2)[1+f_S(s_2)]}{1-f_S(s_1)f_S(s_2)} & \frac{f_S(s_1)f_1(s_2)[1+f_S(s_2)]}{1-f_S(s_1)f_S(s_2)}
\end{bmatrix}$$

Note that

$$(\mu_2^* - \mu_1^*) \frac{1-f_S(s_1)f_S(s_2)}{f_S(s_2)} = \mathbb{E}_f[c(\tilde{\theta})] - \left[\mathbb{E}_f[\tilde{\theta}|\tilde{s} = s_2] - \mathbb{E}_f[\tilde{\theta}|\tilde{s} = s_1]\right]$$

therefore $\mu_2^* \geq \mu_1^*$ if and only if $\mathbb{E}_f[c(\tilde{\theta})] \geq \mathbb{E}_f[\tilde{\theta}|\tilde{s} = s_2] - \mathbb{E}_f[\tilde{\theta}|\tilde{s} = s_1]$.

In conclusion. If $|\mathbb{E}_f[c(\tilde{\theta})]| < \mathbb{E}_f[\tilde{\theta}|\tilde{s} = s_2] - \mathbb{E}_f[\tilde{\theta}|\tilde{s} = s_1]$ only the first order conditions in case 2 can hold. Moreover, it is a maximum because in that case the objective function is strictly concave (see below).

After beliefs have been chosen to minimize expected wages, the principal’s problem is

$$\max_{\{x_1, x_2\}} \left\{ -f_S(s_1)\mathbb{E}_f[(x_1 - \tilde{\theta})^2 | \tilde{s} = s_1] - f_S(s_2)\mathbb{E}_f[(x_2 - \tilde{\theta})^2 | \tilde{s} = s_2] - W(x_1, x_2, \mu_1^*) \right\}$$

The Hessian of the objective function is given by

$$\mathcal{H} = \begin{bmatrix}
-2f_S(s_1) - \frac{\partial^2 W(x_1, x_2, \mu_1^*)}{\partial x_1^2} & -\frac{\partial^2 W(x_1, x_2, \mu_1^*)}{\partial x_1 \partial x_2} \\
-\frac{\partial^2 W(x_1, x_2, \mu_1^*)}{\partial x_1 \partial x_2} & -2f_S(s_2) - \frac{\partial^2 W(x_1, x_2, \mu_1^*)}{\partial x_2^2}
\end{bmatrix}$$

For the second case we have

$$\frac{\partial^2 W(x_1, x_2, \mu_1^*)}{\partial x_1^2} = 2f_S(s_1) (1-f_S(s_2)) = 2f_S(s_1)^2$$

$$\frac{\partial W(x_1, x_2, \mu_1^*)}{\partial x_2^2} = 2f_S(s_2) (1-f_S(s_1)) = 2f_S(s_2)^2$$

$$\frac{\partial^2 W(x_1, x_2, \mu_1^*)}{\partial x_1 \partial x_2} = 2f_S(s_1) f_S(s_2)$$

It follows that in that case the Hessian is negative-definite and the objective function is concave.$\blacksquare$

**Proof of Proposition 5**

We start with the following lemma.
Lemma 1 \( \text{Var}_f(\tilde{s}) = \frac{|f|^2}{f_S(s_1)f_S(s_2)} (\theta_2 - \theta_1)^2. \)

Proof: Using

\[
\begin{align*}
\text{Ef} \left[ E_f \left[ \tilde{\theta} \tilde{s} \right]^2 \right] &= E_f \left[ \tilde{\theta} \tilde{s} = s_2 \right] - f_S(s_1) \left[ E_f \left[ \tilde{\theta} \tilde{s} = s_2 \right] - E_f \left[ \tilde{\theta} \tilde{s} = s_1 \right] \right] + E_f \left[ \tilde{\theta} \tilde{s} = s_1 \right] \\
E_f \left[ \tilde{\theta} \right]^2 &= E_f \left[ \tilde{\theta} \tilde{s} = s_2 \right] - 2 f_S(s_1) E_f \left[ \tilde{\theta} \tilde{s} = s_2 \right] \left[ E_f \left[ \tilde{\theta} \tilde{s} = s_2 \right] - E_f \left[ \tilde{\theta} \tilde{s} = s_1 \right] \right] \\
&\quad + f_S(s_1)^2 \left[ E_f \left[ \tilde{\theta} \tilde{s} = s_2 \right] - E_f \left[ \tilde{\theta} \tilde{s} = s_1 \right] \right]^2 \\
E_f \left[ \tilde{\theta} \tilde{s} = s_2 \right] - E_f \left[ \tilde{\theta} \tilde{s} = s_1 \right] &= \frac{1}{f_S(s_2)} \left[ f(\theta_1, s_2) \theta_1 + f(\theta_2, s_2) \theta_2 \right] - \frac{1}{f_S(s_1)} \left[ f(\theta_1, s_1) \theta_1 + f(\theta_2, s_1) \theta_2 \right]
\end{align*}
\]

we get

\[
\text{Var}_f(\tilde{s}) = \text{Var}_f \left( E_f \left[ \tilde{\theta} \tilde{s} \right] \right) = E_f \left[ E_f \left[ \tilde{\theta} \tilde{s} \right]^2 \right] - E_f \left[ \tilde{\theta} \right]^2
\begin{align*}
&= - f_S(s_1) \left[ E_f \left[ \tilde{\theta} \tilde{s} = s_2 \right] - E_f \left[ \tilde{\theta} \tilde{s} = s_1 \right] \right] \left[ E_f \left[ \tilde{\theta} \tilde{s} = s_2 \right] + E_f \left[ \tilde{\theta} \tilde{s} = s_1 \right] \right] \\
&\quad + 2 f_S(s_1) E_f \left[ \tilde{\theta} \tilde{s} = s_2 \right] \left[ E_f \left[ \tilde{\theta} \tilde{s} = s_2 \right] - E_f \left[ \tilde{\theta} \tilde{s} = s_1 \right] \right] - f_S(s_1)^2 \left[ E_f \left[ \tilde{\theta} \tilde{s} = s_2 \right] - E_f \left[ \tilde{\theta} \tilde{s} = s_1 \right] \right]^2 \\
&\quad = f_S(s_1) \left[ E_f \left[ \tilde{\theta} \tilde{s} = s_2 \right] - E_f \left[ \tilde{\theta} \tilde{s} = s_1 \right] \right] \\
&\quad \left( - \left[ E_f \left[ \tilde{\theta} \tilde{s} = s_2 \right] + E_f \left[ \tilde{\theta} \tilde{s} = s_1 \right] \right] + 2 E_f \left[ \tilde{\theta} \tilde{s} = s_2 \right] - f_S(s_1) \left[ E_f \left[ \tilde{\theta} \tilde{s} = s_2 \right] - E_f \left[ \tilde{\theta} \tilde{s} = s_1 \right] \right] \right) \\
&\quad = f_S(s_1) f_S(s_2) \left[ E_f \left[ \tilde{\theta} \tilde{s} = s_2 \right] - E_f \left[ \tilde{\theta} \tilde{s} = s_1 \right] \right]^2 \\
&\quad = \frac{|f|^2}{f_S(s_1)f_S(s_2)} (\theta_2 - \theta_1)^2
\end{align*}
\]

Delegating to an agent with beliefs \( g^* \) is optimal if and only if

\[
U(g^*) = - \text{Var}_f \left( E_{g^*} [y(\tilde{\theta})] - E_f [\tilde{\theta} \tilde{s}] \right) - E_f \left[ c(\tilde{\theta}) \right]^2 - E_f \left[ \text{Var}_f (\tilde{\theta} \tilde{s}) \right] \geq - \text{Var}_f (\tilde{\theta}).
\]

In any interior optimum we have that \( \text{Var}_f \left( E_{g^*} [y(\tilde{\theta})] - E_f [\tilde{\theta} \tilde{s}] \right) = 0. \) Therefore, this condition is equivalent to

\[
E_f \left[ c(\tilde{\theta}) \right]^2 \leq \text{Var}_f (\tilde{\theta}) - E_f \left[ \text{Var}_f (\tilde{\theta} \tilde{s}) \right] = \text{Var}_f (\tilde{s}).
\]

Using lemma 1 this becomes

\[
E_f \left[ c(\tilde{\theta}) \right]^2 \leq \frac{|f|^2}{f_S(s_1)f_S(s_2)} (\theta_2 - \theta_1)^2
\]
which is equivalent to
\[ f_{S(s_1)}f_{S(s_2)}\mathbb{E}_f \left[ c(\tilde{\theta}) \right]^2 - |f|^2 (y(\theta_2) - y(\theta_1)) (\theta_2 - \theta_1) \leq |f|^2 (\theta_2 - \theta_1)^2 - |f|^2 (y(\theta_2) - y(\theta_1)) (\theta_2 - \theta_1). \]

Therefore
\[ \frac{f_{S(s_1)}f_{S(s_2)}\mathbb{E}_f \left[ c(\tilde{\theta}) \right]^2}{|f| (y(\theta_2) - y(\theta_1)) (\theta_2 - \theta_1)} - |f| \leq \left[ \frac{(\theta_2 - \theta_1)}{y(\theta_2) - y(\theta_1)} - 1 \right] |f| = \varepsilon^* \]

where the definition of \( \varepsilon^* \) follows from the proof of proposition 1.
Appendix B: Alternative specifications

Truth-or-noise information structure

In this appendix I analyze the baseline model described in section 2 under alternative assumptions on the state space and the information structure. Specifically, I assume that the state space is a compact interval, i.e. $\Theta = [\underline{\theta}, \bar{\theta}]$, and that the information structure takes the particular form I describe below.

The agent’s information is represented by an information structure $(S, F)$, where $S \subseteq \mathbb{R}$ is the signal space and $F$ is a c.d.f. over states and signals. Let $F_\Theta$ be marginal c.d.f. of the state under $F$. I assume that the signal equals the state with probability $\rho \in (0, 1)$, otherwise the signal equals an independent draw from $F_\Theta$. Moreover, $F_\Theta$ is assumed to have strictly positive density $f_\Theta$.

In this context, $\rho$ represents the precision of the agent’s information (or, for short, the agent’s precision). Additionally, we consider the case in which the agent can misperceive his precision. Specifically, the agent thinks that his precision equals $\rho + \kappa$ where $\kappa \in [-\rho, 1 - \rho]$. I refer to $\kappa$ as the agent’s level of confidence. We say that the agent is underconfident if $\kappa < 0$, rational if $\kappa = 0$, and overconfident if $\kappa > 0$.

Finally, assume that the principal can select the agent based on his confidence level. The timing of events is as follows

1. Belief design: principal chooses $\kappa \in [-\rho, 1 - \rho]$.
2. Nature draws $(\theta, s)$ according to $F$.
3. Agent observes $s$, interpreting its precision as $\rho + \kappa$, and chooses $x \in \mathbb{R}$.

Payoffs are given by $-(x - \theta)^2$ for the principal and by $-(x - y(\theta))^2$ for the agent. Let $c(\theta) := y(\theta) - \theta$.

The main result in this setting is as follows

**Proposition 6** The unique optimal agent is
Similarly, by under-responsiveness that overconfidence solves. Moreover, the optimal confidence level is given as: 

\[ \kappa^*(\beta) = \begin{cases} 
-\rho & \text{if } \beta \geq 1 \\
-\rho \beta & \text{if } \beta \in (-1 - \rho)/\rho, 1 \\
1 - \rho & \text{if } \beta \leq -(1 - \rho)/\rho 
\end{cases} \]

Proof of proposition 6

Given signal realization \(s\) the optimal action for the agent equals 
\[ x_\kappa(s) = \mathbb{E}_\kappa[y(\tilde{\theta})|\tilde{s} = s] = (\rho + \kappa)y(s) + (1 - \rho - \kappa)\mathbb{E}_F[y(\tilde{\theta})]. \]
Therefore, the principal’s expected payoff is given by 
\[ U(\kappa) := -\mathbb{E}_F[(x_\kappa(s) - \tilde{\theta})^2] = -\mathbb{E}_F[x_\kappa(s)^2] + 2\mathbb{E}_F[x_\kappa(s)\tilde{\theta}] - \mathbb{E}_F[\tilde{\theta}^2]. \]

Note that 
\[ \mathbb{E}_F[x_\kappa(s)^2] = (\rho + \kappa)^2\mathbb{E}_F[y(s)^2] + 2(\rho + \kappa)(1 - \rho - \kappa)\mathbb{E}_F[y(s)]\mathbb{E}_F[y(\tilde{\theta})] + (1 - \rho - \kappa)^2\mathbb{E}_F[y(\tilde{\theta})]^2. \]

Since \(\tilde{s} \sim F_\Theta\), we have that 
\[ \mathbb{E}_F[y(s)^2] = \mathbb{E}_F[y(\tilde{\theta})^2] \text{ and } \mathbb{E}_F[y(s)] = \mathbb{E}_F[y(\tilde{\theta})]. \]
As a result, 
\[ \mathbb{E}_F[x_\kappa(s)^2] = (\rho + \kappa)^2Var_F(y(\tilde{\theta})) + \mathbb{E}_F[y(\tilde{\theta})]^2. \]

Similarly, 
\[ \mathbb{E}_F[x_\kappa(s)\tilde{\theta}] = (\rho + \kappa)\mathbb{E}_F[y(s)\tilde{\theta}] + (1 - \rho - \kappa)\mathbb{E}_F[y(\tilde{\theta})]\mathbb{E}_F[\tilde{\theta}] \]
By the law of iterated expectations we know that
\[
E_F[y(\tilde{s}) \tilde{\theta}] = E_F[y(\tilde{s}) E_F[\tilde{\theta} | \tilde{s}]] \\
= E_F[y(\tilde{s}) \left[ \rho \tilde{s} + (1 - \rho) E_F[\tilde{\theta}] \right]] \\
= \rho E_F[y(\tilde{s}) \tilde{s}] + (1 - \rho) E_F[y(\tilde{s})] E_F[\tilde{\theta}].
\]

Using the fact that \( \tilde{\theta} \) and \( \tilde{s} \) have the same marginal distributions we conclude that
\[
E_F[y(\tilde{s}) \tilde{\theta}] = \rho E_F[y(\tilde{s}) \tilde{s}] + (1 - \rho) E_F[y(\tilde{s})] E_F[\tilde{\theta}] \\
= \rho E_F[y(\tilde{s}) \tilde{s}] + (1 - \rho) E_F[y(\tilde{s})] E_F[\tilde{\theta}].
\]

Taking the derivative of the principal’s expected payoff with respect to the confidence level we get
\[
\frac{\partial U(\kappa)}{\partial \kappa} = -2 \kappa Var_F(y(\tilde{\theta})) + 2 \rho \left[ Cov_F(y(\tilde{\theta}), \tilde{\theta}) - Var_F(y(\tilde{\theta})) \right].
\]

It follows that the principal’s expected payoff is strictly concave in the agent’s level of confidence:
\[
\frac{\partial^2 U(\kappa)}{\partial \kappa^2} = -2 Var_F(y(\tilde{\theta})) < 0.
\]

As a result, there exists a unique level of confidence \( \kappa^*(\beta) \) that maximizes the principal’s expected payoff, which is given by the following expression
\[
\kappa^*(\beta) = \rho \left( \frac{Cov_F(y(\tilde{\theta}), \tilde{\theta})}{Var_F(y(\tilde{\theta}))} - 1 \right) = -\rho \frac{Cov_F(y(\tilde{\theta}), c(\tilde{\theta}))}{Var_F(y(\tilde{\theta}))} = -\rho \beta
\]

Finally, \( \kappa^*(\beta) > -\rho \) is equivalent to \( Cov_F(y(\tilde{\theta}), \tilde{\theta}) / Var_F(y(\tilde{\theta})) > 0 \) and \( \kappa^*(\beta) < 1 - \rho \) is equivalent to \( Cov_F(y(\tilde{\theta}), \tilde{\theta}) / Var_F(y(\tilde{\theta})) < 1 / \rho \). Therefore, \( \kappa^*(\beta) \in (-\rho, 1 - \rho) \) is equivalent to \( \beta \in (-1 - \rho) / \rho, 1) \).
