Just Accepted

“Just Accepted" manuscripts have been peer-reviewed and accepted for publication. They are posted online prior to technical editing, formatting for publication and author proofing. The American Chemical Society provides “Just Accepted” as a free service to the research community to expedite the dissemination of scientific material as soon as possible after acceptance. “Just Accepted” manuscripts appear in full in PDF format accompanied by an HTML abstract. “Just Accepted” manuscripts have been fully peer reviewed, but should not be considered the official version of record. They are accessible to all readers and citable by the Digital Object Identifier (DOI®). “Just Accepted” is an optional service offered to authors. Therefore, the “Just Accepted” Web site may not include all articles that will be published in the journal. After a manuscript is technically edited and formatted, it will be removed from the “Just Accepted” Web site and published as an ASAP article. Note that technical editing may introduce minor changes to the manuscript text and/or graphics which could affect content, and all legal disclaimers and ethical guidelines that apply to the journal pertain. ACS cannot be held responsible for errors or consequences arising from the use of information contained in these “Just Accepted” manuscripts.
Compositional Inhomogeneity and Corner-Enrichment of Pt in Pt/Pd Bimetallic Nanoparticles

Abstract

Experimental results of a smooth composition gradient within Pt/Pd alloy nanoparticles with Pt enrichment at the corners are reported. We find that the Pt concentration gradually increases toward the outermost surface, and it appears different from the thermodynamically most stable configuration. We demonstrate that it is the result from reaction kinetics of both reduction of precursors and growth of nanoparticles, by a growth model. We then explain the corner Pt enrichment is a result of local thermodynamic control at the corners. This mixed control of kinetics and thermodynamics in bimetallic nanoparticle synthesis can lead to the formation of particles with complex concentration profile, which could be interesting when these particles are used in catalytic applications. Our analysis is not simply a qualitative model, rather a relatively rigorous quantitative analysis of the composition as a function of the growth conditions which can serve as a basis for improved reproducibility of synthesis for applications.
Introduction

Metal nanoparticles are of interest due to their unique optical, electrical and catalytic properties, which are different from their monometallic counterparts, and are widely used in various applications.1-3 Their unique physical and chemical properties are dependent on their size, structure and compositions.4-8 Changes in the composition of bimetallic nanoparticles enables tuning of the chemical and physical properties of these particles, for instance the localized surface plasmon resonance (LSPR). 9-10 More studies have been focused on their catalytic behaviors. They offer distinct activities and selectivity different and often better than their monometallic counterparts. 11-15 It has been shown in literature that surface composition changes or surface segregation, i.e. deviation of the surface composition from the bulk, affects the chemical properties of the surface and thus changes the catalytic performances. 16-18 There are recent review articles summarizing how segregation has been predicted theoretically and computationally, as well as providing experimental examples. 6, 15, 19

Most analytical and computational models give the thermodynamically most stable structure, however, many syntheses are kinetically controlled and correspond to kinetic-Wulff shapes as recently reviewed in detail.20 In this paper, we demonstrated a kinetics driven compositional gradient inside Pt/Pd bimetallic multiply twinned particles. Pt/Pd bimetallic nanoparticles are particular of interest owing to their importance in catalysis. 21-23 A gradual increase of Pt within the particle from the center to the outermost surface and an enrichment of Pt at the corners were observed, which was a result of a local thermodynamic control at the corners. We first show via analytical modelling that the compositional gradient is a result of Pt and Pd having different growth rate. We then showed that the corner concentration is related to the weighted mean curvature (chemical potential) of the corner and indicates that the corner concentration of Pt is a
function of Pt and Pd chemical potential in solution. Our analysis is not simply a qualitative model, rather a relatively rigorous quantitative analysis of the composition as a function of the growth conditions which can serve as a basis for improved reproducibility of synthesis for applications.

Experimental Procedure

Synthesis of Pt/Pd alloy multiply-twinned particles was performed via a method developed by Lim et al.\textsuperscript{24} The ratio of Pt and Pd precursors was modified to yield Pt/Pd alloy nanoparticles with different overall concentrations and different degree of Pt corner enrichment. Poly(vinyl pyrrolidone) (PVP, 70mg, MW≈55000) was dissolved in 16mL of deionized water and was heated to 80\degree C in air. Different mole ratio of sodium tetrachloropalladate (II) (Na\textsubscript{2}PdCl\textsubscript{4}) and potassium tetrachloroplatinate(II) (K\textsubscript{2}PtCl\textsubscript{4}) were dissolved in 6mL of deionized water at room temperature. For 1:1 mole ratio solution, 0.032mmol of Na\textsubscript{2}PdCl\textsubscript{4} and 0.032mmol K\textsubscript{2}PtCl\textsubscript{4} were used. The Na\textsubscript{2}PdCl\textsubscript{4} and K\textsubscript{2}PtCl\textsubscript{4} solution was then added to the PVP aqueous solution and the mixture was allowed to react at 80\degree C for 18 hours.

The Pt/Pd alloy nanoparticles were washed 5 times and deposited unto ultra-thin carbon grids. The morphology of the nanoparticles was characterized using a JEOL 2100F Transmission Electron Microscope (TEM) and High-angle Annular Dark Field (HAADF) imaging in an aberration-corrected JEOL JEM-ARM200F Scanning Transmission Electron Microscopes (STEM). The 2D projection of the elemental distribution within the particles was characterized via energy-dispersive x-ray spectroscopy (EDX) using both a Hitachi HD2300 and the JEOL
JEM-ARM200F STEM. In-situ heating experiments were performed using the JEOL 2100F microscope.

We note that the spatial resolution of EDX is dependent on the acceleration voltage and the sample thickness and geometry. In the STEM, the acceleration voltage was 200kV, which was rather high and would lead to a small interaction volume in a thin samples (confirmed by standard Monte Carlo simulations, not shown). The composition quantified from EDX spectra is a 2D projection of the 3D elemental distribution inside the particles.

Results

The product includes different multiply twinned particles, such as truncated/untruncated bipyramids, Marks decahedra (Dh), icosahedra (Ic), and hexagonal platelets. The morphologies of the as-synthesized particles are shown in Figure 1.

The linescans from the corner to the bulk and between two corners indicate Pt enrichment at the surface, especially at the corners. The measured EDX composition profile of particles synthesized with different precursor ratios as a function of distance from the center to the surface, are shown in Figure 2 together with modelling results which will be discussed later. In all cases they show an increase in the Pt concentration away from the center, not simply surface segregation of Pt. A related result is shown in Figure 3, two dimension EDX map of a nanoparticle synthesized using 1:1 molar ratio of Pt and Pd precursors. In addition to the radial composition shown in Figure 2 there is an additional increase in the Pt concentration at corners. This was reproducible, and observed for more than fifty different nanoparticles for this composition of the precursors and other.

Model for Radial Concentration Change
As reviewed recently, the shape of nanoparticles with flat facets can be described in terms of either thermodynamic or kinetic Wulff constructions. We now seek to establish a model based upon these established methods that will account for the concentration profiles. As shown in Figure 2 and 3, the Pt concentration increased toward the surface, and there are three possible explanations for this. The simplest possibility is that the nanoparticles were in their thermodynamic stable configurations and the element with lower surface energy has segregated to the surface. It is well established that surface energy can play an important role in determining the surface composition in alloy systems. For instance, Williams and Nason developed a thermodynamic model predicting surface segregation based on minimizing the surface energy by allowing atoms to exchange between surface layers and the bulk. They suggested that within 4 atomic layers the composition becomes constant. In the same model, they analyzed the effect of chemisorption and size, and compared the model with experimental results. The same method has been used for predicting the surface segregation in Au-Ag bimetallic nanoparticles. More recent works have shown that in nanoparticle systems the surface composition can be altered by chemisorption. For the specific case of Pd/Pt there is experimental and computational results showing that Pd tends to segregate to the surface. According to a recent thermodynamic model, there is a balance between the decrease in surface energy and increase in bulk free energy, which prevents full surface segregation of species to the surface. In such a case we expect that there would be just surface segregation on an otherwise homogeneous bulk alloy nanoparticle. This is not consistent with the present experimental results.

A second possibility is that the concentration gradients are a consequence of inter-diffusion within the nanoparticles. One indicator of this would be Kirkendall voids – none were observed. A more definitive test was an in-situ heating of the sample within an electron
microscope to a temperature of approximately 700°C for 90 mins. There was no evidence of any additional surface segregation or change in the composition. This indicates that diffusion is not dominant, as at these temperatures one would expect much higher mobility than at the synthesis temperature.

The third possibility is that the compositional gradient was not from segregation within the particle, but from the growth kinetics. That growth kinetics can be critical has been known since the early work of Berg\textsuperscript{39} as we have discussed in a recent review.\textsuperscript{20} Since the concentrations of both the Pt and Pd in solution are finite, this will lead to a gradual change in the composition which is consistent with the experimental data. This type of model has been proposed in the existing literature, for instance Ahrenstorf et al. studied the mechanism of formation of Ni/Pt bimetallic nanoparticles and demonstrated that Pt and Ni precursors had different consumption rate\textsuperscript{40} while Choi et al. studied the formation mechanism of Pt/Ni octahedra and demonstrated control of the composition by varying the amount of solvent, precursors and surfactant added,\textsuperscript{41} and they observed the concentration of Pt being richer at the edges and vertices than the center and suggested that the amine group in oleylamine could coordinate with Pt(acac)\textsubscript{2} in the initial stage of the synthesis.\textsuperscript{42} However, quantitative comparisons are currently lacking to substantiate this model.

To develop a model, we first define what is taking place. The PVP was used as the reducing agent. As PdCl\textsubscript{4}\textsuperscript{2-} and PtCl\textsubscript{4}\textsuperscript{2-} are reduced to Pd and Pt monomers, the nucleation stage begins and is followed by growth after the nuclei have reached a critical size. The final products had well defined facets, suggesting that the growth was interface-controlled, i.e. is a kinetic-Wulff mode.\textsuperscript{20, 43-44} The schematics of the formation of these particles is shown in Figure 4. For interface-controlled growth, the rate of growth is limited by the rate of atoms moving from
Region II to Region III in Figure 4 (a). There are monatomic terraces nucleated on an existing flat surface, followed by the growth of this terrace across the facet. According to classical nucleation theory, after the nucleation of the monatomic terrace, the contribution of the bulk free energy will dominate, and the growth of this terrace will be spontaneous and fast, as the free energy of the terrace formation will be negative.

The nanoparticle formation was separated into two steps – reduction of precursors and growth of nanoparticles, because the reduction and growth were on two different time scales. The core of the synthesized nanoparticles had higher Pd concentration and it gradually decreased towards the surface. It indicated that the deposition rate of Pd was higher than that of Pt. The deposition rate had contributions from both reduction of precursors and deposition of reduced monomers.

As the particle growing beyond the critical nucleation size, it was relatively stable and started to grow. The growth was from the flux of the Pt and Pd atoms in the supersaturated solution depositing onto the nanoparticle surface.

The reduction rates are written as,

\[
\begin{align*}
    r(Pd) &= k_{Pd}(T) [PdCl_4^{2-}] [PVP]^2 \\
    r(Pt) &= k_{Pt}(T) [PtCl_4^{2-}] [PVP]^2
\end{align*}
\]

where \(r(Pd)\) and \(r(Pt)\) are the reaction rate of the reduction of Pd and Pt precursors; \(k_{Pd}(T)\) and \(k_{Pt}(T)\) are the reaction rate constants which are dependent upon temperature but independent of reactant concentrations; \([PdCl_4^{2-}]\) and \([PtCl_4^{2-}]\) are the concentrations of Pd and Pt precursors. The reaction temperature was held constant during the reaction, so we will assume that \(k_{Pd}(T)\) and \(k_{Pt}(T)\) are constant for this particular synthesis, and will be written as \(k_{Pd}\) and \(k_{Pt}\) later on.
The Arrhenius equation gives a quantitative definition of reaction rate constant. Simplifying that
the nanoparticles have spherical shapes (which we will return to later), we used a simple
collision model and the ratio between $k_{Pt}$ and $k_{Pd}$ was determined to be 1.035, and the details
were included in Supporting Information.

The deposition rates $R_{Pt}(T)$ and $R_{Pd}(T)$ are proportional to the product of deposition rate
constants, $r_{Pt}(T)$ and $r_{Pt}(T)$, and concentration of reduced Pt and Pd monomers. Our observation
indicated that Pd had a higher deposition rate, and Pd atoms attached to the surface faster than Pt
and it resulted in a Pd rich core. As growth proceeded, Pd atoms were consumed faster than Pt,
and more Pt was deposited near the surface of the nanoparticles and left a concentration gradient
inside the particles.

The concentration profiles were dependent upon the reduction and deposition rates of Pd and Pt
and the incubation time (the nucleation period). The incubation period and ratio between
reduction and deposition rate were determined to have minimal effects on the concentration
profile and the detailed comparisons can be found in Supporting Information. An approximation
was used here that the bigger particles grew at an earlier time than the smaller ones, and all the
particles in the solution stopped growing at the same time (18 hours).

To compare with the experimental results (Figure 2), we first calculated the three-dimensional
concentration profile assuming spherical particles and the reaction kinetics outlined above, then
numerically integrated the composition of Pt as a function of distance along the beam direction
(to match the projected EDX results). We then adjusted the $r_{Pd}(T)/r_{Pt}(T)$ ratio to obtain
reasonable fits to the experimental data using twelve different measurements. We found that the
ratio obtained from the best fits varies with the total amount of precursor molecules added during
synthesis. The $r_{Pd}(T)/r_{Pt}(T)$ ratio as a function of the sum of Pt and Pd precursor concentration is
plotted in Figure 5. The syntheses had the same \( r_{\text{Pd}(T)}/r_{\text{Pt}(T)} \) ratio by adding half the Pd precursors (Pd:Pt precursor = 1:2) and half the Pt precursor (Pd:Pt precursor = 2:1) respectively, and by doubling the amount of Pd precursor and Pt precursor respectively resulted in the same \( r_{\text{Pd}(T)}/r_{\text{Pt}(T)} \) value. The deposition rate constant was independent of the concentration of each precursor but dependent upon the total precursor concentration. As the total precursor concentration increases, the \( r_{\text{Pd}(T)}/r_{\text{Pt}(T)} \) ratio will increase.

As we mentioned above, the shapes of the nanoparticles are not spheres, so we compared the \( r_{\text{Pd}(T)}/r_{\text{Pt}(T)} \) ratio between truncated bipyramids and Marks decahedra synthesized under the same condition and they appear to be similar. The results we obtained from fitting the data with a spherical model might differ from the real \( r_{\text{Pd}(T)}/r_{\text{Pt}(T)} \) ratio, but it is consistent between two dominant shapes in the synthesis.

**Model for Pt Enhancement at the Corners**

Another important observation was that Pt concentration was higher at the corners than that on the surface. To explain this phenomenon, a concept of weighted mean curvature (wmc) should be introduced.\(^{44}\) The weighted mean curvature is the ratio of the change in surface energy and the change in volume. For a simple corner, the chemical potential at an apex can be written as the ratio between the weighted mean surface energy and the truncation along the plane normal. Therefore, the chemical potential goes toward infinity for sharp corners and it is not an artifact of a continuum model as it was verified by density functional calculations. A Lyapunov stable solution will be reached when the external chemical potential equals the chemical potential at the truncated corner.
This Lyapunov stable solution can be extended to the alloy case. This is also analogous to the Stefan problem. At the corner, the differential equation as a function of chemical potentials will be,

$$\frac{ds}{dt} = -a\left(\mu(x_{Pt}) - x_{Pt}\mu^{ext}(Pt) - (1 - x_{Pt})\mu^{ext}(Pd)\right)$$  \hspace{1cm} (3)

where $s$ is the boundary of the corner; $a$ is a constant; $\mu^{ext}$ is the external chemical potential; $\mu(x_{Pt})$ is the chemical potential of the corner as a function of the concentration of Pt at the corner, which can be written as,$^{44}$

$$\mu(x_{Pt}) = \frac{\Omega_o(x_{Pt}\bar{\gamma}_{Pt} + (1 - x_{Pt})\bar{\gamma}_{Pd})}{L - h}$$  \hspace{1cm} (4)

where $L$ is the distance from the Wulff center to the apex of a corner and $h$ the distance from the Wulff center to the truncated surface at a corner; $\Omega_o$ is the atomic volume , and $\bar{\gamma}_{Pt}$ and $\bar{\gamma}_{Pd}$ are the weighted mean surface energy of Pt and Pd assuming the surface energy of Pt/Pd alloy varies linearly between Pt and Pd. The Lyapunov solution is then,

$$x_{Pt} = 1 - \frac{C\mu^{ext}(Pd) - \bar{\gamma}_{Pt}}{C[\mu^{ext}(Pt) - \mu^{ext}(Pd)] + \bar{\gamma}_{Pd}}$$  \hspace{1cm} (5)

where,

$$C = \frac{L - h}{\Omega_o}$$  \hspace{1cm} (6)

The Pt concentration at the corner is plotted as functions of external chemical potentials of Pd and Pt in Figure 6.
The external chemical potential is a function of the Pt and Pd monomer concentrations, and it can be written as,

$$\mu_i = \mu_0 + RT \ln a_i = \mu_0 + RT \ln \frac{b_i}{b_o}$$  \hspace{1cm} (7)$$

where $\mu_0$ is the standard chemical potential of a species, $a_i$ the activity of the species, $\gamma$ the activity coefficient, $b_i$ the molality and $b_o$ the standard molality.

Figure 6(b) shows that with increasing Pd precursor and decreasing Pt precursor concentrations in solution, the concentration of Pt at the corners decreases. In contrast, as the Pd precursor concentration decreases or as the Pt precursor concentration increases in solution, the Pt corner concentration increases. This is consistent with the observed corner Pt concentrations with different amount of precursors added.

**Discussion**

The evidence indicates that for the synthetic conditions herein we have a mixture of control via the reaction kinetics that form the two different monomers and the reaction kinetics of growth with local thermodynamic control at the corners. This is a natural extension of existing models which are well established in the literature.\textsuperscript{20, 44} Such a combination may be of general relevance in many other cases of alloy nanoparticle solution growth; we leave this hypothesis to further work.

From our analysis, the deposition rate constant $r_{Pd}(T)/r_{Pt}(T)$ ratio is ranging from 9-18 at different synthesis conditions and the reduction rate constant ratio $k_{Pd}/k_{Pt}$ is around 1. This implies that the presence of PVP is slowing down the Pt deposition rate. This is consistent with spectroscopic data where there is a larger peak shift of C=O in FTIR spectra for PVP-Pt
compared to PVP-Pd. The stronger interaction between Pt and PVP slows down the deposition of Pt and thus Pd is preferentially deposited onto the surface of the nanoparticles. The concentration of capped PVP at the corners is lower than that at the surface, which results in higher Pt concentration at the corners.

It worth mentioning that the degree of corner enrichment also depends upon the amount of PVP used during synthesis. We can define the degree of corner enrichment as (corner concentration-central bulk concentration)/central bulk concentration. By changing the amount of PVP from the amount reported in the Experimental Procedure section, the degree of corner enrichment for 50%, 100% and 200% PVP are 35%, 100% and 150%, respectively. The corner concentrations (8%, 18%, 50% of Pt) represents the external chemical potential, however, the kinetics still controls the elemental distribution elsewhere. By changing the amount of PVP in this particular reaction can also yield higher corner concentration of Pt. However, the surface appears to be rougher with increasing PVP concentration which indicates that more Cl⁻ ions are produced in solution during reduction and thus the etching from Cl⁻ is more severe for the particles synthesized with bigger amount of PVP added.

There are a lot of mechanistic studies on bimetallic nanoparticle formation of different systems present in literature. Ahrenstorff et al. had studied the mechanism of formation of Ni/Pt bimetallic nanoparticles and demonstrated that Pt and Ni precursors had different consumption rate. Choi et al. had systematically studied the formation mechanism of Pt/Ni octahedra and demonstrated the controlling of the size and composition by varying the amount of solvent, precursors and surfactant added. The Pt/Ru alloy particle formation was also claimed as a result of interdiffusion between a core-shell like structure which was formed from two-step nucleation. Interdiffusion was discussed as a possibility and was found not the case in our system by post-
annealing. Yin et al. had seen PdAg nanoparticles with highly twinned structures formed by coalescence and agglomeration.\textsuperscript{47} In our model, we analyzed the compositional profile in detail and proposed a new model showing the co-exist of kinetic and thermodynamic controls and it helps understand the inhomogeneous elemental distribution in bimetallic nanoparticles and would be beneficial for rational design of novel catalysts.

**Conclusion**

We demonstrated that the smooth composition gradient within the particle is the result of reaction kinetics of monomer formations and growth of particles. The deposition rate constant ratio $r_{\text{Pd}}(T)/r_{\text{Pt}}(T)$ is a function of the total amount of precursors, and is independent of the ratio between Pt and Pd precursors added. The corner Pt enrichment is a result of local thermodynamic control at the corners. The mixed control of kinetics and thermodynamics in bimetallic nanoparticle synthesis can provide particles with complex composition distribution within the particles. More generally, there are opportunities of designing novel bimetallic catalysts utilizing the local elemental enrichments at the corners, where there are more active sites for a variety of catalytic reactions.
