Semiconductor and metal nanoparticles can be exploited as building blocks for designing photonic, electronic, and magnetic devices as well as for use in sensing and optical applications.1–5 Patterned arrays of nanoparticles can even serve as platforms for studying fundamental physical chemistry and molecular interactions.6–8 In particular, the fabrication of ring structures has attracted significant attention due to their applications as optical9–19 and electronic20–23 resonators. Nanoring formation, however, is presently limited by a lack of convenient, inexpensive, and rapid templating methods.4 This problem has motivated considerable efforts to develop improved patterning techniques.21,24–44

One of the most attractive routes for patterning planar surfaces has involved the use of microsphere templates.4,10,34,38,42,45–49 This technique, which is often called colloidal lithography, has been employed for patterning metals, soft matter, and even organic monolayers in regular arrays on solid substrates. Another recent development has involved the use of capillary lithography to direct metal and semiconductor nanoparticles to specific locations in grooves and wells.3,50 We therefore reasoned that arrays of nanoring structures could be formed with a high degree of control by combining colloidal lithography with capillary lithography. Specifically, ~4 nm CdSe QDs were assembled on planar supported substrates containing hexagonal arrays of polystyrene microspheres ranging in size from 200 nm to 2 µm. Well-ordered nanoparticle rings were left behind on the substrate surface after the microspheres were removed. A schematic diagram of this process is shown in Figure 1. The height and width of the rings could be precisely controlled down to the level of single nanoparticle necklaces. Additionally, the diameter of the rings could be defined by the size of the microspheres used for templating.

RESULTS

Forming Quantum Dot Rings by Evaporative Templating. Hexagonal arrays of nanorings made from CdSe QDs were formed by the procedure outlined in Figure 1. In a first step, an aqueous solution containing 2 µm diameter polystyrene spheres was added to a second aqueous solution containing the CdSe quantum dots. The mixture, which contained ~1 × 10^10 spheres/mL and ~1 × 10^14 QDs/mL, was then introduced onto various planar supports in a dropwise fashion (~2 µL droplets). The evaporative templating process was allowed to proceed over an approximately 0.2 cm² area by drying in air at 23 °C with a relative humidity of ~45%. The microspheres were gently removed from the support by applying and removing a piece of adhesive tape to the

ABSTRACT Herein, we demonstrate the controlled formation of two-dimensional periodic arrays of ring-shaped nanostructures assembled from CdSe semiconductor quantum dots (QDs). The patterns were fabricated by using an evaporative templating method. This involves the introduction of an aqueous solution containing both quantum dots and polystyrene microspheres onto the surface of a planar hydrophilic glass substrate. The quantum dots became confined to the meniscus of the microspheres during evaporation, which drove ring assembly via capillary forces at the polystyrene sphere/glass substrate interface. The geometric parameters for nanoring formation could be controlled by tuning the size of the microspheres and the concentration of the QDs employed. This allowed hexagonal arrays of nanorings to be formed with thicknesses ranging from single dot necklaces to thick multilayer structures over surface areas of many square millimeters. Moreover, the diameter of the ring structures could be simultaneously controlled. A simple model was employed to explain the forces involved in the formation of nanoparticle nanorings.

surface. After this, the nanoring array patterns could be directly imaged in air by AFM.

The quality of the patterns depended intimately on the nature of the underlying substrate. For example, hexagonal arrays of nanorings could be formed on glass surfaces; however, some nanoparticles were deposited randomly over the entire surface (Figure 2A). Employing APTMS modified glass left even more material in the background (Figure 2B). This was not surprising as the QDs were acid-terminated and should adhere strongly to the amine-terminated surface via electrostatic and hydrogen bonding interactions. Far better results were achieved by using Shipley 1805 coated (Figure 2C) and PVP-modified glass (Figure 2D) substrates. A key difference between these last two coatings was the fact that hexagonal nanoring patterns could be easily washed away from Shipley 1805 coated surfaces, but not from PVP-modified substrates. Such a result suggested that the interactions between the QDs and the Shipley-coated substrates were very weak. On the other hand, PVP-modified substrates appeared to have an intermediate level of interaction with the QDs. Specifically, the interactions were weak enough to prevent most background particle deposition, yet strong enough to resist rinsing away in water. PVP-modified substrates were therefore used in all subsequent studies.

As noted above, the patterns were typically formed over 0.2 cm² areas. Before their removal, individual polystyrene microspheres forming hexagonal arrays could be seen optically on PVP-coated surfaces. A 60 µm × 45 µm image of one such array is shown in Figure 3A. A few line and point defects can be clearly seen in the image which is typical for colloidal lithography. Additionally, an AFM image of a 20 µm × 20 µm array of CdSe nanorings is shown in Figure 3B. This approximately represents the upper size limit for a region without major defects. Larger regions inevitably contain the common defects of colloidal lithography.

**Verification of Ring Composition.** Next, experiments were performed to verify that the nanorings were made from quantum dots. This was done by repeating the evaporative templating experiments without any quantum dots in the aqueous solution. In this case, no material was deposited on the substrate (data not shown). More direct evidence for QD rings comes from confocal fluorescence microscopy/AFM experiments, which can probe the local optical properties of the surfacemonadsorbed materials with lateral resolution below one micron (488 nm laser excitation and 100 × (0.9 NA) objective). To examine the optical properties of the rings, the sample was immersed in purified water overnight and then rinsed with additional water for 30 s to remove any impurities left on the surface. After this, the sample was dried by blowing N₂ over the surface.

microspheres in solution was held constant at 1 of varying thickness, the concentration of polystyrene size.

ings of these particles were consistent with their larger improved stability of CdSe/ZnS system (peak maximum shifted with respect to solution conditions due to the formation). In that case, the emission was not blue-instead of the smaller CdSe particles (see Supporting Information).52 ZnS nanoparticles with 4 nm peak emission typically found in bulk solution.51 It should be noted, however, that the peak is ~30 nm blue-shifted compared to the 570 nm peak emission typically found in bulk solution.52 This may be due to the surface adsorption of the nanoparticles, their partial oxidation in air, or a combination of both phenomena.53 To test this hypothesis, CdSe/ZnS nanoparticles with ~7.3 nm diameters were used instead of the smaller CdSe particles (see Supporting Information). In that case, the emission was not blue-shifted with respect to solution conditions due to the improved stability of CdSe/ZnS system (peak maximum at 640 nm). Moreover, AFM line profiles from nanorings of these particles were consistent with their larger size.

Controlling the Geometry of the Ring Arrays. To form rings of varying thickness, the concentration of polystyrene microspheres in solution was held constant at 1 × 10 tablets/mL, while the concentration of QDs was varied from 1 × 10 to 1 × 10 QDs/mL (Figure 5). As can be seen, high concentrations of CdSe quantum dots led to the formation of thicker and higher ring structures, while lower concentrations were associated with thinner rings and lower heights. Specifically, AFM topographic height profiles reveal that a ratio of quantum dots to polymer spheres of 10000:1 led to structures that were at least 6 nanoparticle layers high (Figure 5A). When this ratio was reduced to 4000:1, three-layer high structures were observed (Figure 5B). Ratios of 2000:1 and 1000:1 led to two-layer (Figure 5C) and single-layer structures (Figure 5D), respectively. For the two-layer QD rings shown in Figure 5C, each layer exhibited a thickness of ~5 nm and the stacking structure of the QDs within the rings is readily visible in the image. Moreover, individual QDs could be observed when single monolayer high nanorings were formed (Figure 5D). The width of the structure in Figure 5D was about 20–30 nm. This is consistent with the idea that the apparent width should be dominated by the radius of curvature of the AFM tip, which is substantially greater than the diameter of the CdSe QDs. Line profiles of all single rings revealed that they share roughly the same inner contour structure (Figure 5E), which is consistent with the QDs conforming around individual polymer microspheres during the last stage of the drying process.

In a final set of experiments, we wished to verify that the inner radius of the rings could be varied by tuning the size of the polystyrene spheres. This was accomplished by using spheres with diameters ranging from 2 μm down to 200 nm (Figure 6). A line profile across each ring is shown immediately below the corresponding micrograph. These profiles can be used to measure the contact radius, \( R_{\text{ring}} \), as a function of microsphere size. It should be noted that \( R_{\text{ring}} \) was measured at a height of ~4 nm above the plane of the PVP-coated surface, which should correspond roughly to the middle of the lowest layer of nanoparticles. As can be seen, the inner radius contracted from 133 to 43 nm as the size of the microsphere template was shrunk.

A 10 μm × 10 μm image is shown for each template size (2.5 μm × 2.5 μm for 200 nm microsphere template, Figure 7). As can be seen, ring heights and widths were quite uniform from ring to ring. Moreover, the hexagonal pattern was well preserved in all cases except when the smallest polystyrene microspheres were employed. In this case, the CdSe nanorings were more randomly distributed on the substrate. This occurred because the 200 nm microspheres did not form a uniform hexagonal layer. In other words, the colloidal lithography process did not work perfectly for this smallest sphere size.

Figure 5. AFM topographical 3D images of CdSe nanorings obtained from solutions using CdSe to polystyrene microsphere ratios of (A) 10000:1, (B) 4000:1, (C) 2000:1, (D) 1000:1. (E) Line profiles through the center of each ring. The scale bars in each image are 200 nm long.
The value of \( R_{\text{ring}} \) for each microsphere template size could be predicted using a simple hard sphere contact model:

\[
R_{\text{ring}} = \sqrt{(R_{\text{MS}} + R_{\text{QD}})^2 - (R_{\text{MS}} - R_{\text{QD}})^2}
\]

(1)

where \( R_{\text{MS}} \) is the radius of the microspheres, and \( R_{\text{QD}} \) is the radius of quantum dots (Figure 8). Fitting this formula to the four data points from Figure 6 yields a QD radius of \( \sim 4.2 \) nm (Figure 9). Such a value is in excellent agreement with the size of the nanoparticles, whereby the bare CdSe QDs should be \( \sim 2 \) nm in radius and the length of the 16-MHA-capping layer will add slightly more than 2 nm to this value.

**DISCUSSION**

The advantage of using polystyrene microspheres as nanoscale templates is that the wedge-shaped region between the spheres and the planar substrate provides a convenient location for the deposition of the nonvolatile semiconductor particles. Although spheres have been employed in the present case, it is reasonable to hypothesize that other geometries should work as well. For example, arrays of double lines could be formed by using micron-sized rods as templates. Of course, in that case, the ability to form long-range periodic arrays would depend upon developing methods to properly align the rods over long distances. This technique could also be expanded to pattern numerous other materials besides CdSe QDs. As noted above, however, the surface chemistry must be appropriate for high fidelity nanoring formation (Figure 2). If solute particles adhere too strongly or weakly to the substrate, then patterns will either not form at all or be easily damaged merely by rinsing the surface with water. Below, we briefly outline the forces which need to be taken into consideration.

The CdSe QDs become sequestered into the wedge region between the polystyrene spheres and the planar substrate during the evaporation process by a delicate interplay of multiple forces. These include capillary forces, \( F_{\text{cap}} \), and nanoparticle/planar substrate adhesion forces, \( F_{\text{ad}} \). Moreover, the surface of the polystyrene spheres possesses a net negative charge in aqueous solution that is counterbalanced by an ionic double layer.\(^{54}\) Therefore, there should be repulsive interactions between the negatively charged CdSe QDs and the microspheres. This will be manifest as an electrostatic double-layer force, \( F_{\text{dl}} \), whereby the quantum dots can to a first approximation be treated like ions near a charged substrate.\(^{55}\) Capillary forces act to drag the QDs from the water/air interface toward the wedge region, while the nanoparticle/planar substrate adhesion and double-layer forces act to oppose this move-
The capillary force, $F_{\text{cap}}$, can be written as:

$$F_{\text{cap}} = 2\pi r\gamma \cos(\theta)$$

(2)

where $r$ is the contact radius of the water/air interface around the quantum dots (Figure 10), $\gamma$ is the surface tension of water (0.073 N/m at 293 K), and $\theta$ is the contact angle, which can be taken to be $\sim 30^\circ$. Under these conditions, the maximum radius is limited to the radius of the 16-MHA-capped quantum dots. Therefore, $r_{\text{max}} = 4$ nm and $F_{\text{cap}} \leq 1.6$ nN. Most of this force should be parallel to the plane of the surface; however, a small component will be normal to it. It should also be noted that the total capillary interaction energy between the nanoparticles and microspheres can be estimated by integrating from $r = 0$ to $r_{\text{max}}$. This interaction energy is $\sim 400kT$, which suggests that capillary interactions dominate over thermal fluctuations.

The electrostatic double layer force, $F_{\text{dl, imp}}$, in simplified form can be written as:

$$F_{\text{dl, imp}} = 8\pi \varepsilon_0 A \kappa^{-1}$$

(3)

where $A$ is the Hamaker constant for the PVP-QD system in water, $R$ is the CdSe QD radius, $z_0$ is distance between the edge of the QD and the planar surface, and $a$ is the contact radius. The value of this last constant would presumably be related to the deformation of the 16-MHA-capping layer as well as any deformation in the PVP layer (Figure 11). For 4 nm radius nanoparticles on planar substrates under ambient conditions, the contact radius, $a$, should be $\sim 2$ nm according to continuum elastic theory using the MD (Maugis–Dugdale) transition model. The value of $A$ can be estimated to be approximately $2 \times 10^{-20}$ J based upon literature values for similar systems.

Moreover, based upon the Bohr radius of the atoms on the substrate surface and QDs, it is often estimated that $z_0$ should be $\sim 0.4$ nm. This leads to $F_{\text{ad}} = \sim 0.3$ nN for QDs with $R = 4$ nm.

The vectorial addition of $F_{\text{dl}} + F_{\text{dl, imp}}$ would have a maximum value of 1.3 nN if they were in the same direction; however, they are not (Figure 10). They would add to approximately 1.1 nN for $\phi = 80^\circ$. This situation occurs as the first layer of nanoparticles approaches the contact ring. Projecting this magnitude onto the direction perpendicular to the surface normal would provide a force of 0.6 nN opposite to the direction of $F_{\text{cap}}$. This would make the combination of these two forces considerably smaller than the component of $F_{\text{cap}}$, which is parallel to the surface. It should be noted that this total vector sum will also be opposed by a kinetic friction component, $F_f$, which will also impede the progress of the nanoparticles in the direction of the contact ring.

It is almost certainly the case that $F_{\text{cap}}$ exceeds $F_{\text{ad}} + F_{\text{dl}} + F_f$ for all the systems that were examined in Fig-

Figure 10. Schematic diagram showing the forces involved in dragging the CdSe quantum dots (shown in red) to the polystyrene spheres (shown in orange). Note that the drawing is not to scale. Moreover, there is almost certainly a hydration layer that coats the entire hydrophilic CdSe quantum dot, which has not been explicitly drawn. Therefore, the capillary force must exceed the combination of the other two in order for nanorings to form. These forces along with the corresponding frictional drag force, $F_f$, which also impedes the movement of the nanoparticles, are summarized in Figure 10 and will be discussed below.

The capillary force, $F_{\text{cap}}$, can be written as:

$$F_{\text{cap}} = 2\pi r\gamma \cos(\theta)$$

(4)

where $A$ is the Hamaker constant for the PVP-QD system in water, $R$ is the CdSe QD radius, $z_0$ is distance between the edge of the QD and the planar surface, and $a$ is the contact radius. The value of this last constant would presumably be related to the deformation of the 16-MHA-capping layer as well as any deformation in the PVP layer (Figure 11). For 4 nm radius nanoparticles on planar substrates under ambient conditions, the contact radius, $a$, should be $\sim 2$ nm according to continuum elastic theory using the MD (Maugis–Dugdale) transition model. The value of $A$ can be estimated to be approximately $2 \times 10^{-20}$ J based upon literature values for similar systems.

Moreover, based upon the Bohr radius of the atoms on the substrate surface and QDs, it is often estimated that $z_0$ should be $\sim 0.4$ nm. This leads to $F_{\text{ad}} = \sim 0.3$ nN for QDs with $R = 4$ nm.

The vectorial addition of $F_{\text{dl}} + F_{\text{dl, imp}}$ would have a maximum value of 1.3 nN if they were in the same direction; however, they are not (Figure 10). They would add to approximately 1.1 nN for $\phi = 80^\circ$. This situation occurs as the first layer of nanoparticles approaches the contact ring. Projecting this magnitude onto the direction perpendicular to the surface normal would provide a force of 0.6 nN opposite to the direction of $F_{\text{cap}}$. This would make the combination of these two forces considerably smaller than the component of $F_{\text{cap}}$, which is parallel to the surface. It should be noted that this total vector sum will also be opposed by a kinetic friction component, $F_f$, which will also impede the progress of the nanoparticles in the direction of the contact ring.

It is almost certainly the case that $F_{\text{cap}}$ exceeds $F_{\text{ad}} + F_{\text{dl}} + F_f$ for all the systems that were examined in Fig.
ure 2. Indeed, rings were formed in all four cases. In Figure 2A,B, however, a significant fraction of CdSe QDs were adsorbed sporadically on the planar substrates rather than at the contact ring. This is almost certainly due to the fact that the adhesion force varies greatly as a function of position. Indeed, defects and related strong interaction sites probably pin the CdSe QDs at specific locations.

Finally, the above calculations lead to the notion that there should be an upper limit to the size of nanoparticles which can be templated by this combined colloidal lithography/capillary lithography technique. This is because the double-layer force will increase faster than the capillary force as the nanoparticle size increases. Specifically, the capillary force increases linearly with nanoparticle radius, while the double-layer force increases as the square of the radius. Based upon the equations above, one would expect the limit to be reached for ~30 nm nanoparticles when 2 μm polymer spheres are employed in conjunction with PVP-coated substrates.

METHODS

Synthesis of CdSe Nanoparticles. Trioctylphosphine oxide (TOPO)-capped spherical CdSe nanocrystals were prepared from CdO and Se by employing a well-established solvolothermal method.\(^\text{66}\) Initially, 250 mg of CdO was heated to 300 °C in a mixture of trioctylphosphate oxide (1.15 g), hexadecylamine (2.85 g), and tetradecylphosphonic acid (1.09 g) under a nitrogen atmosphere. After the solution became optically clear, 0.5 g of tributylphosphine was added and the temperature was reduced to 260 °C. Eighty milligrams of selenium dissolved in 0.72 g of tributylphosphine was quickly injected into this mixture to initiate the formation of the nanocrystals. When the desired size of the nanocrystals was reached, the reaction mixture was cooled down to 60 °C and 10 g of nonanoic acid was added. The nanocrystals were purified by repeated precipitation/suspension cycles in methanol and toluene. Passivation of the CdSe nanocrystals with 16-mercaptotetradecanecanoic acid (16-MHA) was performed by heating the TOPO-capped CdSe nanocrystals in methanolic solutions of 16-MHA and tetraethylammonium hydroxide at 65 °C for 6 h under refluxing conditions.\(^\text{66}\) The resulting MHA-capped CdSe nanocrystals were soluble in water and, as expected, exhibited reduced fluorescence compared to TOPO-capped nanocrystals. The average diameter of the CdSe QDs was determined by transmission electron microscopy (TEM) (Figure S1 in Supporting Information). The value was 4.0 ± 0.3 nm, which corresponds only to the semiconductor nanocrystal core and not the 16-MHA coating. This is not surprising, as it is difficult to observe the organic monolayer film by TEM. The concentration of nanoparticle solution was obtained from UV–vis absorption spectrum and the absorption cross section of CdSe nanocrystals.\(^\text{67}\)

Microsphere Preparation. Polystyrene microspheres were purchased from Duke Scientific (Fremont, CA). The spheres were repeatedly centrifuged for 5 min at 9300g (10000 rpm, Eppendorf Centrifuge 5415D, Hamburg Germany) and resuspended in ultrapure water (18.2 MΩ cm, NANOpure, Barnstead, Dubuque, IA) to remove surfactant molecules from the solution. This centrifugation/resuspension process was typically repeated eight times.

Preparation of Substrates. Glass cover slides (VWR) were cleaned in piranha solution (1:3 H₂O₂/H₂SO₄) and then annealed to 450 °C and held at that temperature for 5 h (Caution: Piranha is a vigorous oxidant and should be used with extreme caution). Next, the clean glass slides were modified by placing a recently cleaned glass slide into a 1 mM APTMS/ethanol solution overnight followed by rinsing with ethanol and water. Finally, the slides were dried by blowing compressed nitrogen gas over the surface. Shipley 1805 films were obtained by spin coating a clean glass slide with a 1:5 mixture of Shipley 1805 and Thinner P (Microchem, Newton, MA) and polyvinylpyrrolidone (PVP, Sigma-Aldrich, Mn = 55000). APTMS-modified glass was obtained by placing a recently cleaned glass slide into a 1 mM APTMS/ethanol solution overnight followed by rinsing with ethanol and water. Finally, the slides were dried by blowing compressed nitrogen gas over the surface. Shipley 1805 films were obtained by spin coating a clean glass slide with a 1:5 mixture of Shipley 1805 and Thinner P (Microchem, MA). The substrates were then baked for 1 min at 90 °C followed by further annealing to 120 °C for 1 min. PVP-modified surfaces were prepared by soaking freshly prepared glass substrates in a 1% PVP ethanol solution overnight. The samples were then rinsed sequentially with ethanol and purified water for 1 min each. Finally, the samples were dried by blowing nitrogen gas over the surface.

Surface Imaging. Atomic force microscopy (AFM) images were taken with a Nanoscope IIIa Multimode scanning probe microscope (Veeco-Digital Instruments) using NSC15/NoAl ultrasharp tapping mode tips (Micromash; tip radius ~10 nm; average spring constant 40 N/m). Additional images were captured with a WITec Alpha300 combined confocal fluorescence/AFM system to allow for sequential confocal fluorescence and AFM imaging of the same area. For fluorescence imaging, the nanocrystals were excited with an Ar⁺ laser was used as the excitation source. Optical micrographs were captured with a Nikon high numerical aperture objective (100×, 0.9 NA). Spectral data were acquired with an Acton triple grating spectrometer imaged onto an Andor Peltier cooled (~70 °C) CCD detector. Fluorescence images were generated from integrated spectra acquired between 500 and 600 nm.
