ABSTRACT The power conversion efficiency of photovoltaic devices based on semiconductor perovskites has reached ~20% after just several years of research efforts. With concomitant discoveries of other promising applications in lasers, light-emitting diodes, and photodetectors, it is natural to anticipate what further excitement these exotic perovskites could bring about. Here we report on the observation of single photon emission from single CsPbBr₃ perovskite nanocrystals (NCs) synthesized from a facile colloidal approach. Compared with traditional metal-chalcogenide NCs, these CsPbBr₃ NCs exhibit nearly 2 orders of magnitude increase in their absorption cross sections at similar emission colors. Moreover, the radiative lifetime of CsPbBr₃ NCs is greatly shortened at both room and cryogenic temperatures to favor an extremely fast output of single photons. The above superior optical properties have paved the way toward quantum-light applications of perovskite NCs in various quantum information processing schemes.

S

ingle optical emitters such as natural atoms¹ and molecules² are able to emit single photons due to the time interval needed for the electron to recycle between the two-level ground and excited states. This kind of quantum-light emission has been intensively pursued and manipulated since it can provide a robust platform to test fundamental quantum-optical and measurement theories as well as to promote practical quantum information processing applications in terms of quantum computing, teleportation, and cryptography.³,⁴ So far, single photon emission has been discovered in a very limited number of artificially engineered fluorescent materials ranging from epitaxial quantum dots (QDs),⁵ colloidal nanocrystals (NCs),⁶ and diamond color centers⁷ to carbon nanotubes⁸ and most recently to Pr³⁺:YAG crystals,⁹ 4H-SiC wafers,¹⁰ and atomically thin layers of 2D WS₂.¹¹ Most of the above single photon sources are associated with structural/compositional defects whose exact origins are sometimes illusive, while only epitaxial QDs and colloidal NCs can be predictably and reproducibly produced with size- and shape-dependent optical properties dictated by the quantum confinement effect. When the selection criterion for single photon sources is raised even higher to be more relevant to practical applications, colloidal NCs are eventually singled out as the unique candidate capable of emitting visible light at room temperature. After nearly two decades of intensive research, a rich spectrum of optical phenomena has been revealed from colloidal NCs at the single-particle level,¹² the understanding of which is continuously promoting their potential applications such as in biotechnology, medicine, electronics, and optoelectronics.¹³ One open question of immediate importance is whether a brand new class of colloidal NCs, other than the current ones based almost solely on metal chalcogenides (e.g., CdSe NCs), can be
Semiconductor perovskites can be conveniently described by the formula ABX₃ with A, B, and X being an organic or inorganic cation, a metal cation, and a halide anion, respectively. Within just the last several years, the power conversion efficiency of solar cells incorporating perovskites as light harvesters has been dramatically increased from the original ~3.8% to the current value of ~20%. This stunning performance of perovskites in solar cells largely stems from their easy solution processing, suitable energy gap, and high absorption coefficients, in addition to the high mobility, long diffusion length, and slow radiative recombination of photoexcited charge carriers. These unique material and optical properties of perovskites can also be applied to several other optoelectronic devices, with their debut appearances in light-emitting diodes, lasers, and photodetectors having been sequentially demonstrated. To bring the remaining potentials of perovskites into full play, it is imperative to obtain a deeper understanding of the underlying photophysics and to fabricate larger-sized single crystals with lower densities of structural defects and carrier traps. Meanwhile, with several initial attempts to reduce the size of bulk perovskites to the submicrometer scale, colloidal NCs of both cesium halide anions have been recently synthesized. These achievements not only provide a flexible tunability for the size-dependent fluorescent colors of perovskites but also prepare a necessary condition to explore their quantum-light nature of single photon emissions.

Here we focus on optical characterizations of single CsPbBr₃ (cesium lead bromide) perovskite NCs whose sizes are close to the exciton Bohr diameter to reach the quantum-confined regime. At room temperature, the photoluminescence (PL) intensity of single CsPbBr₃ NCs switched between the “on” and “off” periods intermittently (also called blinking), which can be attributed to random formation of charged excitons and the associated nonradiative Auger recombination. The same Auger process also greatly suppressed the radiative recombination of multie excitons, leading to almost complete single photon emissions from single CsPbBr₃ NCs. At cryogenic temperature, the PL line width of a single NC was as broad as ~1 meV under the influence of the spectral diffusion effect. While the above optical behaviors are on par with those observed in conventional metal-chalcogenide NCs, these CsPbBr₃ NCs have exhibited a nearly 2 orders of magnitude increase in their absorption cross sections. Moreover, the PL lifetime of single NCs is greatly shortened at both room and cryogenic temperatures to favor an extremely fast output of single photons.

(d) PL intensity of ensemble CsPbBr₃ NCs measured as a function of the laser power density P and fitted with the function $I = I_{0} - \alpha P$, where $I_{0}$ is a fitting constant related to the absorption cross section.

RESULTS AND DISCUSSION

According to a previous report, perovskite CsPbBr₃ NCs used in the current experiment were synthesized from a colloidal approach (see Experimental Section) with a cubic shape and an average size of ~9.4 nm, as estimated from the transmission electron microscopy measurement (Figure 1a,b). The NC dimension is close to the Bohr diameter of ~7 nm estimated for the Wannier–Mott excitons of CsPbBr₃ perovskites, so that the quantum confinement effect can be expected. The first absorption band and the PL peak measured from ensemble CsPbBr₃ NCs are located at ~504 nm (~2.46 eV) and ~511 nm (~2.43 eV), respectively (Figure 1c), corresponding to an energy gap that is blue-shifted by ~200 meV relative to the bulk value of ~2.25 eV. With pulsed laser excitation at 405 nm, we measured the PL intensity of ensemble CsPbBr₃ NCs as a function of the laser power density (Figure 1d). For bulk perovskite films, the PL intensity increases almost continuously with the increasing laser power density, which is usually accompanied by a blue shift and an obvious broadening of the PL spectrum due to the band-filling effect. Then the PL saturation effect (Figure 1d) and the invariant PL line shape (see Supporting Information, Figure S1) measured for ensemble CsPbBr₃ NCs with increasing laser power densities are strong evidence that optical emissions originate from atomic-like, discrete energy levels.

With the excitation of the same 405 nm pulsed laser, we further performed optical characterizations of single CsPbBr₃ NCs at room temperature unless otherwise specified in the text (see Experimental Section). In Figure 2a, we plot a confocal scanning PL image acquired from a sample region of 10 μm × 10 μm, where each bright spot corresponds to the optical...
emission from a single CsPbBr$_3$ NC. The PL spectra of three single CsPbBr$_3$ NCs are shown in Figure 2b with an average fwhm (full width at half-maximum) of $\sim$100 meV ($\sim$25 nm). Due to the inhomogeneous size distribution (Figure 1a,b), these PL peaks vary in the range $\sim$505–515 nm, which is a clear demonstration of the size-dependent energy gaps of the CsPbBr$_3$ NCs. In Figure 2c, we also plot the PL intensity of a representative single NC as a function of the laser power density, and a similar PL saturation effect to the one shown in Figure 1d for ensemble NCs can be observed. With $\langle N \rangle$ representing the average number of photons absorbed per NC per pulse, the PL saturation curve can be fitted with a functional form $\propto 1 - e^{-\alpha P}$, where $\alpha$ is a fitting constant related to the absorption cross section. (d) PL decay curve of a single CsPbBr$_3$ NC fitted by a single-exponential function with a radiative lifetime of $\sim$6.44 ns.

The PL time trajectory of a representative CsPbBr$_3$ NC is shown in Figure 3a with an obvious PL blinking behavior, which was observed from all the single CsPbBr$_3$ NCs studied in our experiment (see Supporting Information Figure S3 for the PL time trajectories of two additional NCs). The probability densities for the time durations of both blinking “on” and “off” periods roughly follow an inverse power-law distribution with an exponent of $\sim$1.5 (see Supporting Information, Figure S4). Similar to the case of single CdSe NCs, the blinking “off” periods can be attributed to non-radiative Auger recombination of charged excitons formed after the photoexcited electron or hole is captured by an external trap and the subsequent excitation of another electron–hole pair in the single NC. While being negligible in bulk semiconductors, the Auger effect manifests itself strongly in quantum-confined NCs due to the enhanced Coulomb interaction between charge carriers and the alleviated kinematic restriction on momentum conservation.$^{39}$ In fact, the existence of Auger interaction between charge

carriers in a single NC is a prerequisite for single photon emission since it provides an efficient channel for nonradiative dissipation of multiexcitons to prevent simultaneous emission of multiple photons.\textsuperscript{37} The PL blinking phenomenon recently reported in both CH\textsubscript{3}NH\textsubscript{3}PbI\textsubscript{3} (ref 40) and CH\textsubscript{3}NH\textsubscript{3}PbBr\textsubscript{3} (ref 41) perovskite particles, whose dimensions are much larger than the exciton Bohr diameters, might be caused by some other mechanisms instead of Auger recombination of charged excitons since no single photon emission was observed at the single-particle level.

Single photon emissions were observed in all the single CsPbBr\textsubscript{3} NCs studied in our experiment from the second-order autocorrelation function \(g^{(2)}(t)\) measurements. With the continuous wave (CW) excitation from a 400 nm laser, the ratio between \(g^{(2)}(0)\) and \(g^{(2)}(t)\) at long time delays was calculated to be \(\sim 0.06\) for a representative NC (Figure 3b). With the pulsed excitation from the 405 nm laser, the average area ratio between the central \(g^{(2)}(0)\) and the side \(g^{(2)}(nT)\) peaks was calculated to be \(\sim 0.06\) for another representative NC (Figure 3c), where \(n \geq 1\) is an integer and \(T\) is the laser repetition time. These excellent photon antibunching features strongly confirm that single CsPbBr\textsubscript{3} NCs can serve perfectly as a single photon source. In our experiment, we also increased the laser power density to set \(\langle N \rangle\) larger than \(\sim 1.0\) so that the possibility for the generation of multiexcitons in a single NC should be greatly increased.\textsuperscript{37,39} As can be seen in Supporting Information Figure S5 for the pulsed excitation of a representative NC, there was almost no increase in the average area ratio between the central and the side peaks with the increasing laser power density. This implies that Auger recombination of multiexcitons is extremely efficient in single CsPbBr\textsubscript{3} NCs, thus rendering a pure single photon stream without random interruptions of multiphoton events.

We have also performed optical characterizations of CsPbBr\textsubscript{3} NCs at the cryogenic temperature of \(\sim 4\) K. Consistent with what was reported previously for bulk CH\textsubscript{3}NH\textsubscript{2}PbI\textsubscript{3} perovskites,\textsuperscript{35} the PL peak measured at \(\sim 4\) K for ensemble CsPbBr\textsubscript{3} NCs showed no blue shift when compared to the one measured at room temperature (see Supporting Information, Figure S6). In Figure 4a, we plot the PL spectra of four single CsPbBr\textsubscript{3} NCs with the calculated FWHMs that are all slightly smaller than 1 meV. These relatively broad PL spectra reflect the fact that spectral diffusion is still drastic at \(\sim 4\) K, as can be seen from the time-dependent PL spectral image shown in Figure 4b for two single CsPbBr\textsubscript{3} NCs. The PL decay curve of a representative CsPbBr\textsubscript{3} NC is shown in Figure 4c, which can be fitted well only by a biexponential function with a fast and a slow lifetime component of \(\sim 355\) ps and \(\sim 5.75\) ns, respectively (see Supporting Information Figure S7 for the PL decay curves of two additional CsPbBr\textsubscript{3} NCs). For single CdSe NCs, the PL decay also becomes biexponential at cryogenic temperatures due to electronically coupled optical emissions from a bright state and a lower-lying dark state with a radiative lifetime of hundreds of nanoseconds.\textsuperscript{32} The energy-level splitting between the above two states can reach the scale of several millielectronvolts, so that the long-lived dark state cannot be easily depopulated by the thermal energy at cryogenic temperatures, leading to its dominant contribution to the total optical emissions over the bright state in CdSe NCs. If thermal mixing of bright and dark states can really be invoked to explain the PL dynamics observed here for single CsPbBr\textsubscript{3} NCs, their energy-level splitting must be significantly smaller than that in CdSe NCs since the slow lifetime component of \(\sim 5.75\) ns accounts for at most \(\sim 5\%\) of the total PL decay.

On the basis of all the experimental results obtained so far, we would like to point out several superior optical properties of the newly synthesized perovskite NCs over traditional metal-chalcogenide NCs. First, to achieve the same brightness, the laser power density used to excite a single perovskite NC can be decreased by almost 2 orders of magnitude due to the enhanced absorption cross section. This would greatly reduce the possibility of tissue damage in biolabeling and bioimaging studies, the scattered laser light under resonant or near-resonant excitation conditions, and the working current in electrically driven lightening devices. Second, although the perovskite NCs studied here have a PL peak around \(\sim 510\) nm, the sizes and compositions can be further manipulated to render broad fluorescent colors spanning the green-to-red wavelength range of traditional metal-chalcogenide NCs. Moreover, the PL peaks of perovskite NCs can be potentially extended to even shorter wavelengths, e.g., with the...
that single photon emission was also discovered in ability of emitting single photons. It should be noted skite NCs can be used as a highly efficient, pure single photon source driven at high repetition rates of $\sim 1$ GHz.

**CONCLUSIONS**

To summarize, we have synthesized colloidal CsPbBr$_3$ NCs and successfully demonstrated their capability of emitting single photons. It should be noted that single photon emission was also discovered in single perovskite CsPbI$_3$ NCs in a very recent report, which focused mainly on their PL blinking behavior and multie exciton Auger process. In contrast, we here explore discrepancies between the optical properties of traditional metal-chalcogenide CdSe NCs and the newly synthesized perovskite CsPbBr$_3$ NCs, the latter of which have demonstrated 2 orders of magnitude increase of the absorption cross section and several times decrease of the radiative lifetime. Moreover, the dark-exciton emission commonly encountered in metal-chalcogenide CdSe NCs is almost missing in perovskite CsPbBr$_3$ NCs, signifying a huge difference in the electronic structures of these two types of NC materials. The introduction of perovskite NC optical emitters to the colloidal NC and semiconductor perovskite families will surely stimulate intensive research efforts in future works of material synthesis, fundamental science, and device application. Since perovskite NCs have just come into play in the research community, there is much room for the optimization of the material properties by borrowing nearly two decades of synthesis protocols developed for metal-chalcogenide NCs. For example, proper selection of the passivation ligands and wise adoption of core/shell structures would certainly help to boost the fluorescent quantum efficiency with robust photostability, as well as to suppress or even eliminate the PL blinking and spectral diffusion effects. From the fundamental science point of view, a lot of intriguing issues need to be addressed for single perovskite NCs especially at cryogenic temperatures, including the fine-structure splitting of bright and dark states, as well as the magneto-optical and the coherent properties. Given the fact that the fabrication techniques for solar cells, light-emitting diodes, and photodetectors based on bulk perovskite films have been fully developed, it would also be interesting to see how perovskite NCs behave in these optoelectronic devices.

**EXPERIMENTAL SECTION**

**Synthesis of Colloidal CsPbBr$_3$ NCs.** Chemicals: Cs$_2$CO$_3$ (99.9%) was purchased from J&K. Oleic acid (90%), OA) and octadecene (90%, ODE) were purchased from Alfa Aesar. PbBr$_2$ (99.0%) and oleylamine (80–90%, OLA) were purchased from Aladdin. Toluen (99.9%) was purchased from Beijing Chemical Factory.

**Preparation of Cs-Oleate.** Cs$_2$CO$_3$ (0.8 g), OA (2.5 mL), and ODE (30 mL) were loaded into a 100 mL three-neck flask and dried under vacuum for 1 h at 120 °C. The reaction solution was then kept at 150 °C under N$_2$ until it became clear.

**Synthesis and Purification of CsPbBr$_3$ NCs.** ODE (10 mL) and PbBr$_2$ (0.138g) were added into a 50 mL three-neck flask and dried under vacuum for 1 h at 120 °C. Then, dried OLA (1 mL) and dried OA (1 mL) were injected under N$_2$. After the mixture became clear, the temperature was raised to 180 °C and the Cs-oleate solution (0.8 mL, 0.1 M in ODE, preheated to 100 °C) was quickly injected. The reaction mixture was kept at this temperature for 5 s and then was cooled to room temperature by an ice–water bath. The final NCs were purified by centrifugation and redispersed in toluene to form a long-term colloidal solution.

**Calculations of Absorption Cross Sections.** The PL saturation curve of either ensemble or single CsPbBr$_3$ NCs can be fitted with a functional form $F = 1 - e^{\beta P N A}$, where $\beta$ and $j$ are the absorption cross section and the laser pump fluence, respectively. The pump fluence $j$ can be calculated from $j = \gamma P/F$, where the laser power density $P$ can be directly measured, $F$ is the laser repetition rate of 5 MHz, and $E$ is the laser photon energy at 405 nm. Based on the above procedures, the absorption cross sections estimated for ensemble CsPbBr$_3$ NCs and a representative CsPbBr$_3$ NC are $-2.33 \times 10^{-15}$ and $-1.33 \times 10^{-15}$ cm$^2$, respectively. For comparison, commercial Qdot525 colloidal NCs from Invitrogen have a peak emission wavelength of $\sim 525$ nm and a molar extinction coefficient $\varepsilon$ of $360 \times 10^3$ M$^{-1} \text{cm}^{-1}$ at 405 nm. The absorption cross section $\sigma$ of Qdot525 NCs can be calculated to be $1.38 \times 10^{-13}$ cm$^2$ from $\sigma = \varepsilon N_A$, where $N_A$ is Avogadro’s number.
